TRACHEOTOMY IN CROUP:

WITH REMARKS ON

THE PATHOLOGY, DIAGNOSIS, PROGNOSIS AND TREATMENT OF THE DISEASE, AND THE CAUSES OF DEATH IN FATAL CASES; WITH A REPORT OF THIRTY-FIVE OPERATIONS.

By JOHN H. RIPLEY, M.D.,

SURGEON TO CHARITY HOSPITAL; PHYSICIAN TO ST. FRANCIS'S HOSPITAL, NEW YORK CITY.

PART I.

THE article herewith presented is designed to illustrate some of the more important facts in relation to croup. The subject is an important one. Hundreds of children in this city alone annually perish from this dread malady, many of them without a final effort being made to rescue them from death by suffocation; and this, too, in spite of the fact that tracheotomy is the most successful method of treatment hitherto devised. The accompanying histories of cases are full, but uncolored. They exhibit the different types of membranous croup as it has prevailed in this city during the last few years, and especially the course it pursues when the lives of its victims are prolonged by tracheotomy. To those interested in the subject, the details will not, I believe, be considered unimportant. The labor required in compiling these notes can only be appreciated by those who have done similar work. The remarks following have been suggested by clinical observation. It will be a satisfaction to know that the paper contributes, in any degree, to the better understanding of this terrible disease.

CASE I.—M. M——, female, Irish, three and a half years old; previously healthy. Had been sick three days with hoarseness and croupy cough. Until last night the mother did not consider the child in danger. During the night she got very much troubled for breath, and has since been getting worse. Emetics had been tried with negative results. I found her with flushed face, head thrown back, and labored, stridulous respirations. There was supraclavicular and epigastric depression with each inspiration. Her pulse was 120; respiration, 40; temperature, 103°. No swelling about the neck. The fauces presented nothing abnormal on inspection; no congestion, no membrane. The lungs were generally tympanitic on percussion, and all ascultatory sounds masked by the laryngeal. Tracheotomy, under chloroform, was at once performed, Drs. A. C. Graham and E. A. Maxwell assisting. No membrane was seen during the operation. The relief was complete, and everything remained favorable during the following twenty-four hours. The respirations and pulse became less frequent, and the temperature fell to 101.5°. Forty-eight hours after the operation the temperature had risen to 102.5°; the respiration had become somewhat sawing in quality and more rapid. There was a profuse discharge of muco-purulent, though not bad-smelling matter, through the tube, and the inner canula needed frequent cleansings. Occasionally, a teaspoonful of warm water was poured into the tube, which gave temporary relief by exciting violent coughing, and thereby expelling small pieces of membrane and other obstructing material. The disease slowly progressed downward, and she died eighty-two hours after the operation, dyspnœa being the most prominent symptom during the last day of life. There was no swelling of the tonsils nor lymphatics of the neck, and no membrane was seen either on the wound or in the pharynx during the progress of the case. The treatment consisted in the internal administration of a solution of five grains of chlorate of potassa every two hours and the free use of stimulants and nourishment. The temperature of the room was kept at about 80° F., and the atmosphere impregnated with steam. No case of diphtheria or croup had preceded this (which was in a tenement-house), and none followed it, at least for several weeks, although two young children of the family were in the same rooms while the sister was sick.

CASE II.—L. F——, two and one-half years old, of Irish parentage, had been sick two days. Loss of appetite, fever, sore throat, gradually increasing hoarseness with dyspnœa, worse at night, had been the symptoms noticed. I saw her in the evening with the attending physician, Dr. Burton. She had a flushed countenance, dry, barking cough, stridulous breathing, and moderate dyspnœa. Temperature, 103°; pulse, 120. No membrane to be seen either in the throat or nares; no swelling of the glands. General appearance not indicative of systemic poisoning. Tracheotomy was performed at once, and afforded complete relief. No membrane seen during the operation. The following morning there was some swelling of the neck, so as to render it necessary to loosen the tapes, and a portion of the wound gaped. The temperature was 103.5°, and the pulse 130. Both tonsils were covered with a grayish membrane, and the child's general condition unfavorable. In the evening of the same day the neck had become enormously swollen; there was a thin, fetid, acrid discharge from the anterior nares; the surfaces of the wound and both the hard and soft palate were covered with a thick, blackish-gray membrane. Her extremities were cold and the pulse was very rapid and feeble; there was also internal strabismus of the left eye, the conjunctiva of both being injected and swollen. The countenance had a leaden hue. During the night she had several convulsions, in the last of which she expired, thirty-six hours after the operation. No other children in the family. The treatment consisted in the administration of a solution of chlorate of potassa and the muriated tincture of iron, and stimulants. The temperature of the room varied. Steam was constantly evolved from a kettle of boiling clothes in the room during the child's sickness.

CASE III.—Jacobs, male, four years old; a previously strong and healthy child; was first seen by me April 29, 1874. He had been sick four days with slowly progressive croup symptoms. No vomiting, and no marked constitutional disturbance.

Thirty-six hours before I saw him, in the evening, he began to suffer from dyspnœa, which had been steadily getting worse. He was well advanced in the second stage when I saw him. Face pale, cold, and perspiring; lips and fingers blue; great dyspnœa. No swelling of the neck, and no membrane to be seen. Pulse rapid and feeble; temperature, 103°. Drs. V. P. Gibney, Jacob D. Rogers, and N. G. McMaster assisted me in performing tracheotomy, about an hour later. The operation was simple and bloodless, and gave complete relief. Ten hours later he seemed to be doing well: pulse, 130; respiration, 32; temperature, 102°. The following morning (April 30th), twenty-four hours after the operation, he had more fever: pulse, 150; respiration, 34; temperature, 103°. Evening: pulse, 140; respiration, 42; temperature, 102°. Some erysipelas around the lower portion of the wound. May 1st, 10 A.M.: pulse, 140; respiration, 40; temperature 102°. Erysipelas now involves the whole of the upper surface of the chest. 10 P.M.: pulse, 140; respiration, 40; temperature, 103. Erysipelas about the same. The child is very restless, the cough constant and harassing, and the respiration "sawing." As I thought there might be less irritation if the tube were out, I removed it, and cut out a piece of the trachea about half an inch square. About 2 o'clock the following morning I was sent for, because the child was supposed to be dying. I found him pulseless, with face livid, eyeballs turned upward and pupils widely dilated, and respiration nearly suspended. The cause was apparent. He had turned his head half around, so as to twist the neck and so bring together the lips of the external wound in the neck, almost completely shutting off the admission of air to the lungs. By simply untwisting the neck the respiration soon became re-established, and all of these terrible symptoms rapidly disappeared. As no improvement had followed having the tube out, and as this accident might again happen, with only stupid people to watch the child if it remained out, I replaced it. The cough was so harassing and the dyspnœa so great, that I resorted to various plans for the purpose of modifying them. Water poured into the trachea would temporarily relieve, but the exhaustion following the violent cough excited by this procedure more than counterbalanced the good obtained. Clearing the trachea and primary bronchi, by means of a small sponge fastened to a delicate pair of laryngeal forceps, was discontinued for the same reason. The only satisfactory relief was obtained from the direct inhalation of either simple or lime steam. In spite of all efforts, however, he died in the afternoon of the same day, seventy-six hours after the operation, dyspnœa remaining the most prominent symptom to the last. Four other young children in the family were constantly by his crib during his sickness, but did not subsequently suffer from the disease. Chlorate of potassa and the muriate of iron, and stimulants, made up the constitutional treatment in this case.

CASE IV.—This was a delicate male infant, one year old. He had been ill of naso-pharyngeal diphtheria for several days, but the laryngeal symptoms had been observed only twenty-four hours preceding the time that I saw him with Dr. Burton. Although suffering from grave systemic poisoning, we thought it right to give him the chance of an operation, as laryngeal dyspnœa was, at that time, the predominant symptom. Drs. Burton and J. D. Rogers assisted me in doing tracheotomy. Twice during the operation respiration became suspended, and was again restored by the method of Marshall Hall. Several pieces of membrane were removed from the wound in the trachea before introducing the tube. He came out quickly from the chloroform, and was doing well when we left. Three hours later he suddenly stopped breathing, and his face became livid. His mother attempted to remove the tube, but did not succeed—being too much frightened, and immediately sent for the doctor; when Dr. Burton arrived the child was dead. On removing the tube he found it completely occluded by a piece of membrane.

CASE V.—P. T. L., age seven years, complained of sore throat on Friday night. On Saturday he had some fever, and during the night the mother noticed that he breathed hard. Sunday he was in bed, and for the first time was observed to be a little hoarse. Monday he was about the room, though still hoarse, and at night his breathing was more obstructed. Tuesday morning I saw him. He was then breathing with great effort, and was somewhat cyanotic. No swelling of the neck or glands, no congestion of the fauces, and no membrane to be seen. Pulse, 140 and strong; temperature not taken. I proposed tracheotomy. Emetics of various kinds had been given without result. A consultation was held, at the request of the parents, with Drs. M. Herzog and H. F. Walker, who fully agreed with me in regard to the case, and kindly consented to assist in the operation. No accident happened during its performance, and the relief was complete. Four hours after the operation the temperature was 102°, and the pulse 140. The following day the respiration became hurried and sawing, the pulse steadily increased in frequency, and, although several large pieces of membrane were expelled through the tube during the day, no relief followed. Wednesday night there was some nausea and vomiting, great restlessness and dyspnœa. The anxious, cyanotic countenance, and terrible struggles for air, were very painful to witness. Death took place at 5 A.M., Thursday morning.

No membrane appeared above the larynx during the progress of the disease, and there was no swelling of the cervical glands. A solution of chlorate of potassa was given after the operation. Either steam, or the vapor of lime, was perseveringly used until a few hours preceding death. A young child of the same family escaped infection, although allowed to remain with its sick brother.

CASE VI.—G. D——, aged six years, was taken suddenly ill in the evening with fever, sore throat, nausea, and vomiting. During the night he was restless, and at times would complain that he could not get his breath. In the morning following there was some hoarseness, and the attacks of dyspnœa became more severe and prolonged. In the afternoon he suffered constantly with exacerbations, during which the parents several times thought him to be dying. I saw him at four P.M. He then had labored, whistling inspiration, accompanied with infrasternal and supraclavicular depression, while expiration was comparatively easy and noiseless. Both tonsils and the soft palate were very much swollen, and of a dark mahogany color, but I saw no membrane. The temperature was 102°, and the pulse 120. I did not think it safe to await the trial of medicine, and did tracheotomy at once, Drs. W. A. Hawes and W. A. Fanning assisting. Chloroform, as usual, diminished the dyspnœa. No membrane was seen during the operation. Respiration became easy, slow, and noiseless soon after the tube was introduced. The next morning the patient was bright and doing well, but the sutures had all given way, and the parts about the wound were infiltrated and red. On the second day after the operation the temperature was 101°, respiration 24, pulse 110. Wound was covered with a thick yellowish white membrane, a specimen of which was examined by Dr. Delafield. There was considerable cough and expectoration through the tube, but, otherwise, the patient was doing well. Swelling of the throat diminishing. Stenosis of the larynx about the same as before the operation. From this date the case progressed favorably. The tube was removed on the fifth day. Membrane remained on the wound until the seventh day, and while it remained, there was no attempt at cicatrization. But as soon as it disappeared the opening closed rapidly, so that by the twelfth day respiration was carried on entirely through the larynx. Chlorate of potassa, iron, and stimulants were given internally. No local treatment except a pad of oakum over the wound after the removal of the tube.

Case VII.—T. E——, a delicate boy, twenty-three months old, was seen first on the 8th, and had then been sick two days. Had had some fever, but had refused food because it hurt his mouth. He lay listless in his crib, the saliva dribbling from his unclosed mouth, and a profuse discharge of mucus from the nose. The whole buccal membrane was studded with small ulcers, the pharynx was entirely covered with membrane, and a small patch was observed on the left tonsil. Temperature 100°.

9th.—Membrane has extended over both tonsils, and there is growing hoarseness, with croupy cough.

10th.—The laryngeal symptoms have steadily increased, and there is now urgent dyspnœa. Tracheotomy was suggested to the parents as affording the only chance of saving the child, but it was not urged. The mother said : "If it will save suffering only, do it." Before the operation the respirations were 48 per minute. Chloroform was given, and a tube introduced without delay. Membrane could be seen lining the trachea after it was opened, but was too soft to strip off. The breathing immediately became easy and noiseless, but remained rapid—44 per minute—although there were no physical signs of lung-infiltration.

11th.—Very little change in the patient's condition until this afternoon, when the neck and face began to swell, and the respirations to become noisy. The temperature rose to 102.5° and the pulse to 160 per minute. Refuses food and medicine.

12th.—The swelling of the neck increased from yesterday, and life terminated in a convulsion at noon to-day. Chlorate of potassa and iron were given freely as long as the patient could be induced to take anything. An elder brother had a mild attack of diphtheria and recovered.

Case VIII.—K. McK——, three and a half years old, had been sick with naso-pharyngeal diphtheria four days when croup developed, and I saw her still a day later. The croup was then far advanced in the second stage. Chloroform was given by Dr. W. A. Hawes, with his usual care and excellent judgment. Everything progressed favorably with the operation until a moment or two after the tube was introduced, when, the anæsthetic having meantime been withheld, the patient's respiration suddenly ceased, her pupils dilated, and the body became limp and motionless. The head was immediately lowered, and artificial respiration resorted to ; but, although we continued our efforts some fifteen or twenty minutes, we did not succeed in restoring animation. Permission was given us to prolong the tracheal incision and examine the interior of the larynx and trachea. Both were lined with a soft, adherent, grayish white membrane, but no detached pieces were seen.

Case IX.—On the 8th of December, Kate L——, a fair-haired, slender little girl, æt. six and a half years, was sent to St. Francis's Hospital by Dr. Schlereth, my house physician. She had then been sick eight days. The earlier symptoms had been loss of appetite, fever, vomiting, and painful deglutition. On the third day of her sickness white specks were observed on the tonsils by the mother, and the family barber was called in. December 5th, the throat symptoms had become much worse, and a croupy cough with dyspnœa was developed. Free emesis by means of squills afforded temporary relief, but the following day (December 6th) the difficulty in respiration had become alarming, and Dr. S. was sent for. He found the patient with a pulse of 150 and temperature of 103°. The face was cyanotic, breathing labored and stridulous, neck swollen, and soft palate, and tonsils partially covered with a whitish membrane. He ordered an emetic of sulphate of copper, which resulted in the expulsion of a firm, tough, cylindrical piece of membrane, two inches in length and one-quarter of an inch in diameter. Marked relief followed, and for several hours the child continued to do well, but during the night the laryngeal symptoms became aggravated. December 7th, her pulse was 160, respiration 30, temperature 103½°, and she suffered much from dyspnœa. Emetics were again resorted to, but with negative results. Temporary relief was afforded by giving chloroform and vapor of lime by inhalation. When brought to the hospital the following day, there was complete aphonia, labored respiration, with the usual supraclavicular and epigastric depressions during inspiration. Her face was pale and anxious, and lips livid. There was nothing abnormal to be seen in the anterior nares, but both tonsils were swollen and partly coated with a yellowish white membrane. There was tympanitic resonance on percussion over the greater part of both lungs. Conveyed sounds from the larynx, and large mucous and sonorous râles, were all that could be heard on auscultation. Chloroform was now administered preparatory to tracheotomy, which immediately modified the labored breathing. The trachea was reached without difficulty. On opening it and introducing the dilators, a large amount of frothy muco-purulent matter welled up through the wound, and, a moment later, a large semicylindrical piece of membrane was coughed up into it, but before it could be caught it was sucked back by the inspiratory act, and the breathing suddenly stopped. A violent cough followed, the membrane was again thrown into the opening, and this time seized with a pair of dressing-forceps and removed. Several smaller pieces were subsequently expelled, and when all was clear the canula was substituted for the dilators, and the wound of the soft parts closed. The breathing soon became tranquil, and all cyanosis disappeared. Vesicular respiration could be heard over all parts of the lungs, accompanied with large mucous râles. Six hours later, in the evening, the temperature was 101°, pulse 120, respiration 30. She had a severe suffocative attack an hour later, which terminated on the expulsion of a portion of detached membrane through the tube. The case progressed favorably till December 12th, when the respirations became somewhat hurried and noisy, although the temperature and pulse were not materially altered. Dr. Edel, our curator, who was present at this time, suggested spraying the air-passages with a weak solution (gtt. xv., ad aq. ℥ j.) of the spirits of turpentine. This was done, and the breathing speedily improved. Its use, ten minutes at a time, at intervals of two hours, was continued for two days, although there was no special indication after the first trial.

December 16th.—Patient has been doing well since last report. Urine has been examined chemically and found to contain a small amount of albumen. Spherical bacteria were seen on microscopic examination of portions of membrane. Removed the tube temporarily, and placed a piece of oiled-silk over the wound, when it was found necessary to replace it as there was still too much laryngeal obstruction.

December 18th.—The larynx was examined to-day with the mirror, and, although considerably congested, was found free from membrane. Tube removed. Some difficulty experienced at first in breathing through the larynx, but after a few hours it became much lessened. The wound closed perfectly in about ten days, and the child was discharged from the hospital. No paralyses were noticed during two weeks following the removal of the tube. Five grains of chlorate of potassa every two hours were given during the first three days, and the same with five drops of mur. tinct. of iron for two days more, and then, no medicines.

Case X.—K., male, æt. five years, was thought to have a cold in the head a week ago (Oct. 26, 1875). Dr. Hawes was called yesterday and found the child hoarse and also slight laryngeal obstruction. To-day (Nov. 2d) there is great dyspnœa with complete aphonia. No glandular swelling nor cellular infiltration. A small patch of membrane adheres to the left tonsil; pulse, 140; respiration, 30; temperature, 103°. Tracheotomy at once performed, Drs. Hawes and S. S. Jones assisting. Trachea deep; no hemorrhage or other accident. The boy rallied well from the chloroform and breathed easily and noiselessly. I did not see him again, but learned from Dr. H. that the respiration became noisy and difficult on the second day after the operation, and that death took place on the third day after the operation, with the same train of symptoms as that which usually accompanies a case of unrelieved croup.

This iron and potash mixture was given regularly by Dr. Hawes during his attendance on the case. No steam.

Case XI.—Lottie G——, æt. three and a half years, was said to have had a cold in the head, for four days when I saw her, Oct. 6, 1875. On examination, membrane was seen in both nares and on both tonsils. There was also some engorgement of the cervical glands. She had slight fever, was a little hoarse, but still was playing about the room with other children. 7th.—She had a great deal of dyspnœa during the night, but this morning there is not sufficient obstruction to deter her from engaging in her customary amusements. There is also a diminution of the glandular swelling and also of the membrane on the tonsils. 8th.—Was sent for in great haste at 9 A.M. I found the child moribund. The respiration was irregular and gasping, the pulse almost absent, the extremities cold, the face dusky. Dr. Hawes had also been sent for, but had not yet arrived, and so I began the operation of tracheotomy with the assistance of the father. Dr. H. arrived a moment later and gave chloroform during two or three inspirations; but, as the child did not struggle, it was entirely withheld during the remainder of the operation. No time was lost, and we were soon within the trachea. The dilators were immediately introduced, but respiration stopped, and we were compelled to induce it artificially and continue it for several minutes before it became voluntary. Meantime much muco-purulent matter had been removed from the trachea. The tube was then introduced but accidentally slipped out again as we were applying the tapes, and again respiration ceased. The dilators were then reintroduced and artificial respiration a second time resorted to successfully. Finally, after the lapse of half an hour or so, the tube having been replaced and stimulants given, voluntary breathing was established. Two hours later the child was conscious and had taken nourishment. There was considerable erythema of the neck in the region of the wound, and the surface of the body and limbs was hot; pulse, 168; respiration, 56. 9 P.M.—Pulse, 160; respiration, 62; temperature, 103°. The lungs are clear except a few mucous râles, and there is not much discharge from the tube.

9th, 10 A.M.—The patient has slept well during the night and coughed little. She is bright and cheerful. Pulse, 142; respiration, 40; temperature, 102⅗°. 6 P.M.—Still looking well; pulse, 144; respiration, 36.

10th.—The neck began swelling last evening, and this morning there is great tumefaction, especially about the throat and upper part of the chest, and these parts are also red. A few bullæ have formed in the neighborhood of the wound. There is considerable cough, and a thick, sanguineo-purulent matter, containing also shreds of membrane, is being expelled through the tube. The respirations are free and 24 per minute; pulse, 138; temperature, 102°. The child is still quite comfortable and takes nourishment well. Five drops of the tincture of chloride of iron, to be taken every two hours, were ordered, and a solution of carbolic acid to be applied over the erysipelatous parts. 5 P.M.—The redness has extended, but the swelling remains about the same. Child playing with pennies; pulse, 126; respiration, 28.

11th, 10 A.M.—Redness has extended upward, especially on the left side, where it reaches the ear; but it is less intense than yesterday, and the swelling is generally less. The patient had a comfortable night, and still looks well. Cough moderate. On removing the tube and closing the wound, the larynx is found impermeable. 9 P.M.—Some increase of the swelling; otherwise the same.

12th, 10 A.M.—Redness still extending. Some discharge of bloody matter through the tube, and a little from the mouth. Larynx slightly permeable. Pulse, 140; respiration, 20; temperature, 101½°. 9 P.M.—Redness has reached the ears on both sides, and involves the roots of the hair posteriorly. Child still bright. Pulse, 128; respiration, 28.

13th, 10 A.M.—Child playing with her doll. Discharge of pus and blood from tube rather profuse. Pulse, 144; respiration, 28; temperature, 100½°. 6 P.M.—The respiration is noisy and difficult, and the child looks weary and anxious. The cough is very troublesome, and the bronchial and tracheal secretion profuse. Respiration, 36.

14th, 10 A.M.—The respirations are rapid and sawing. The usual signs of bronchial obstruction—depression of the supraclavicular and infracostal spaces during inspiration—are present. The poor, doomed little girl is still trying to play with her pennies and doll, notwithstanding the face is becoming dusky and the extremities cold. It is a sad picture and a very discouraging one!

15th.—Died at 11 o'clock last night.

Case XII.—N——, a feeble boy, twenty-three months old, who had a small, unsymmetrical head, syphilitic teeth, and had not yet learned to talk, had been suffering from croup two days. At the time I saw him (Feb. 6, 1878), the usual signs of laryngeal obstruction in an advanced stage were well-marked, although no membrane was to be seen in any of the air-passages. Pulse, 154; respiration, 32; temperature, 101°. The lungs were tympanitic on percussion. Little true respiratory murmur could be heard, only the laryngeal stridor and a few moist râles. Dr. Milne, the attending physician, and Dr. Daniel Lewis assisted me in doing tracheotomy. Only a small amount of blood was lost during the operation, and this was black and thick. Eight hours after the operation (5 P.M.) the breathing was still rapid, although comparatively easy. By pouring warm, dilute lime-water into the tube and immediately turning the patient on his face, a considerable quantity of muco-purulent matter and shreds of soft membrane was coughed up and the breathing rendered less frequent. The lungs were clear. Pulse, 170; respiration, 50; temperature, 105°. The internal treatment is to consist of small doses of calomel and iodide of potassium three times a day, given separately, and the free use of milk and brandy.

7th, 10 A.M.—Had some diarrhœa during the night, but otherwise was quite comfortable. At six o'clock this morning the breathing became very much obstructed, and Dr. Milne was sent for, but before his arrival the patient got relief, after coughing up "phlegm and some hard, tough pieces." Pulse, 156; respiration, 48; temperature, 102¾°. The specifics to be omitted on account of diarrhœa, and a single dose of six grains of quinine to be given. 6 P.M.—Breathes noiselessly and easily, and has been playing some during the day. Iodide of potassium has been resumed. Pulse, 150; respiration, 48; temperature, 102½°.

8th, 10 A.M.—The cough and expectoration have been excessive, but otherwise his symptoms are rather favorable. Pulse, 132; respiration, 38; temperature, 101°. Medicine discontinued. Temperature of room, 80°. Steam is being constantly evolved from a kettle of boiling clothes. 9th.—Symptoms remain about the same; larynx impermeable. Pulse, 140; respiration, 32; temperature, 101°.

10th, 6 P.M.—A change for the worse. The prominent symptoms are: difficult breathing, restlessness, and great weakness. Wound looks bad. Profuse tracheal discharge. No membrane to be seen except what is expelled through the tube. Tube changed for a longer and larger one, but without much benefit. Pulse, 146; respiration, 44; temperature, 103°. Lungs mostly tympanitic, but some areas of dulness. Breathing asthmatic.

11th, 10 A.M.—Boy steadily getting worse. His countenance is very pale, and his cough feeble. Refuses food. Pulse, 160; respiration, 68; temperature, 101⅘°.

12th.—Died at 1.30 this morning.

Case XIII.—D——, male, five years old, was taken sick January 25, 1878, with fever and vomiting. Dr. Milne saw him on the second day of his illness, and found both tonsils covered with membrane, but the constitutional symptoms so slight as not to compel the patient to take to his bed. After three days' attendance the doctor discontinued his visits, at the request of the parents, they believing the child out of danger, although membrane still remained on the tonsils. The patient continued to do well until February 4th, when a croupy cough was developed. February 6th, Dr. M. was again called on account of supervening dyspnœa. He at once advised tracheotomy, and, the parents consenting, he asked me to do the operation. At this time dyspnœa was extreme and aphonia complete. Membrane on both tonsils. Pulse, 128; respiration, 36; temperature, 90¾°. The operation was unusually difficult, the trachea lying deep, the veins numerous and engorged, and the isthmus very large. The hemorrhage was inconsiderable. A considerable quantity of muco-pus welled up through the wound after incising the trachea, and two large, semicylindrical pieces of tough membrane, half an inch long, were expelled through the opening after introducing the dilators. Soon after the tube was in place, the breathing became easy and noiseless.

February 7, 10 A.M.—Pulse, 152; respiration, 44; temperature, 101½°. Has had a good night, and is bright and playful. Respiration noiseless. 6 P.M.—Pulse, 132; respiration, 44; temperature, 102¾°. Very little discharge from the tube, and the skin is hot and dry; otherwise, condition favorable. A diaphoretic mixture was ordered.

8th, 10 A.M.—Pulse, 138; respiration, 38; temperature, 101⅖°. The boy has passed a restless night. There is a good deal of inflammatory œdema over the upper part of the sternum and anterior aspect of the neck. The skin is moist and breathing quiet. As the tube was not freely movable, it was resolved to replace it with a smaller and shorter one. While making the change, several pieces of membrane were coughed up, one of which was bifurcate. Child gets much exhausted after any little exertion, becomes pale, and perspiration breaks out over the body. 6 P.M.—The swelling of the neck has so much increased that the tube does not reach through the tracheal opening, and serious dyspnœa is the result. The original tube is again inserted with some difficulty; more membrane is expelled, after which the breathing is again easy.

9th, 10 A.M.—Pulse, 132; respiration, 28; temperature, 101⅘°. Another restless night; neck and chest still swollen, and the wound covered with a thick, yellowish membrane. There has been a profuse expectoration of muco-pus and some blood, through the night. Chlorate of potassa, in ten-grain doses, has been given every two hours since the operation, and is still continued. 6 P.M.—Pulse, 140; respiration, 40; temperature, 104°. Local symptoms unchanged. The cough is frequent and dry, but respiration is not harsh, and a physical examination of the chest gives negative results. Ordered five grains of quinine, to be repeated after an hour.

10th, 10 A.M.—During the latter part of the night the dyspnœa became very distressing, and was not relieved by cleansing the inner tube; the parents, therefore, as they had been previously instructed to do, removed both *cannulæ*, and left them out until our arrival. The breathing was still difficult when we saw him, but on reintroducing the tube, violent coughing was excited, a quantity of loose membrane and pus was expectorated, which afforded much relief. 5 P.M.—Pulse, 130; respiration, 38; temperature, 102⅓°. Local swelling diminished. Membrane still on tonsils. Fifteen grains of quinine, in three separate doses, have been given to-day. Steam from a croup-kettle has been constantly breathed since morning, with apparently good effect, and is to be continued.

11th, 10 A.M.—Pulse, 138; respiration, 32; temperature, 102⅗°. General appearance of patient is unfavorable. He lies listless upon his back, and offers of pennies or toys, which have heretofore excited his interest, now produce no effect. The one favorable symptom is unobstructed respiration. The chlorate of potassa is to be temporarily discontinued, and a solution containing a grain of bromine to each dose is to be given every two hours instead. 5.30 P.M.—Condition unchanged. Bromine and steam to be continued.

12th, 10 A.M.—Pulse, 120; respiration, 40; temperature, 102°. The breathing still free, although there has been a profuse expectoration of bloody matter during the night. The tube is perfectly movable within the trachea. Membrane still on both tonsils.

6 P.M.—Redness has extended over the whole of the infraclavicular and left scapular regions, but the swelling about the wound is less, as shown by the puckering of the integuments. His general appearance is better, and his appetite is returning. Bromine to be given every three, and five drops of tincture of iron every two hours, and steam continued.

13th, 10 A.M.—Pulse, 130; temperature, 101°; respiration, 40. Erysipelas subsiding. Considerable hemorrhage through the tube during the night, and this morning an attack of dyspnœa due to plugging of tube with a large clot, which was expelled by coughing. After cleansing the canula, the respirations fell to 28 per minute.

14th, 10 A.M.—Pulse, 124; respiration, 40; temperature, 101½°. Membrane has disappeared from tonsils. The tube was temporarily removed, and a piece of oiled silk stretched over the tracheal opening. Asphyxia immediately supervened, as hardly any air could be obtained through the larynx. Lungs clear. 5.30 P.M.—Pulse, 116; respiration, 36; temperature, 100⅓°. Complete aphonia.

15th, 10 A.M.—Pulse, 120; temperature, 100; respiration, 20. An attempt to make a laryngoscopic examination failed.

16th, 10 A.M.—A tolerably satisfactory examination with the mirror discovers no membrane in the larynx. Tube removed, and oakum applied over the wound. Boy can speak aloud. Temperature, 100.°

17th.—Wound looks well. Patient does not eat so well to-day. Breathes mostly through tracheal wound. Purulent discharge profuse. Temperature, 100½°.

April 19th.—I did not see the patient again after the above report, but learned from Dr. M. that his recovery was perfect, and that the tracheal wound was completely closed in about a week after the removal of the tube.

To be continued.

◆

ENDORSING HIGHER MEDICAL EDUCATION.—At the last meeting of the Michigan Medical Society, the following resolution was unanimously adopted:

"*Resolved*, That we, the members of the Michigan Medical Society, pledge ourselves, individually and collectively, to support only such schools as require for admission a preliminary examination, and for graduation at least a three term graded course of lectures in three years of study, and that we will use our influence to prevent students from attending any college with an inferior standard of preparation and graduation"

All the medical schools of Michigan have adopted a three term graded course.

RELATION OF NERVE-LESIONS TO MUSCULAR SPASM AND RIGIDITY.

By THOMAS W. POOLE, M.D.,

LINDSAY, ONTARIO, CANADA,

EXAMINER IN PHYSIOLOGY, HISTOLOGY, AND BOTANY FOR THE MEDICAL COUNCIL OF THE PROVINCE OF ONTARIO; AUTHOR OF "PHYSIOLOGICAL THERAPEUTICS."

THE frequent association of motor-nerve incompetency, or paralysis, with muscular spasm and rigidity, cannot for a moment be called in question. Certain lesions of the brain and cord may exist without producing either, and certain other lesions, or rather lesions of certain special tracts, as certainly are attended by both motor paralysis and muscular rigidity. To discuss the relations of such lesions to the muscles, and their character—whether "irritating" (in the sense of evoking increased nerve-power) or paralyzing—is the object of this paper.

M. Charcot attributes "the relative benignity" and usually temporary character of the hemiplegia resulting from lesions of the gray ganglia of the brain (corpora striata, thalami, etc.) to the fact that, owing to peculiarities of their blood-supply, an entire ganglion is rarely affected, and also to the manner in which each of these ganglia aid or supplement the functions of the others ("Local Dis. Brain," p. 78). The same reasons serve to account for the absence of spasm or rigidity under similar conditions. When, however, hemorrhage or other destructive lesion occurs in the peduncle, where motor fibres from a large area converge to form the isthmus, or "internal capsule," a smaller lesion may work much greater mischief, because in this case nervous communication is seriously interrupted or cut off between the gray motor ganglia and the periphery, so that, although "the patient survives, there will remain *persistent paralysis and permanent contractions* (Ib., p. 7).

It is to "truly destructive lesions of the internal capsule"—that is, "to those which either by lacerations or necrosis produce an irreparable loss of substance" (p. 79)—that allusion is here made. Such lesions can hardly be other than of an essentially paralyzing character; and the "paralysis" and "contractions" which follow are fairly assignable to a common cause: that cause being absence of motor-nerve influence, at once releasing the muscle from the control of the will (paralysis) and setting it free from nervous restraint, thereby permitting the free exercise of its inherent property of contractility, and so inducing rigidity.

Is there any mode of escape from such a conclusion as this? Will it be said that, while it is true that normal nerve-force is here arrested, the lesion is the source of an abnormal or morbid nerve-force, which, acting as the *alter ego* or substitute for nerve-force proper, "stimulates" the muscles to contract unduly? Such a supposition requires us to believe that there are two kinds of nerve-force, and that the spurious variety is not of a simply negative character, but that it is a positively acting or effective force, and that it may be evoked and display its activity under conditions which are fatal to nerve-force proper. Surely there is nothing in physiology to justify such a hypothesis!

Or will it be said that at the distal extremity of the destructive lesion an "irritation" is set up in the adjacent healthy nerve-tissue of the peduncle, from which increased energy is transmitted to the cord and thence to the muscles, as the stimulus to occasion muscular spasm or rigidity? Perhaps the best answer to this is to be found in the fact that the lesion under consideration is a type of those cranial lesions which result in atrophy, degeneration, and destruction of certain nervous fasciculi of the spinal cord by the process known as consecutive or secondary sclerosis, as a consequence of which "the cord loses both in the ability to transmit and to generate nerve-force." In this fact, then, is a further bar to any supposed excitation reaching the muscles from the hypothetical "irritation" referred to. Besides, such a source of a *quasi* nerve-power would be necessarily too transient and too feeble to produce the effects witnessed, for, according to M. Charcot, "these lesions produce a motor paralysis almost necessarily accompanied by late contractions" (p. 78), which often continue for months and years.

Then, again, early rigidity often occurs very promptly as a result of large lesions of the brain, "seriously implicating some extent of the cortical gray matter and destroying a considerable area of the subjacent white substance." This rigidity may even occur "while the patient is still in a state of apoplectic or epileptiform stupor" (Bastian: "Paral. from Brain Dis.," p. 154). Now, it cannot be claimed that here the muscular rigidity is due to "irritation" of the cerebral motor centres, because the "stupor" referred to is itself presumptive evidence of paralysis; and besides, Dr. Ferrier holds that this portion of the brain is insensible to mechanical irritation, even when applied in the actual cautery. If, then, muscular rigidity thus occurs in one form of brain-lesion, where a hypothetical "irritation" is necessarily precluded, and is the outcome of an essentially paralyzing process, it is fair to infer that when muscular rigidity follows similar processes destructive of important motor tracts, as in the case of the inner capsule, the same condition predominates, and that, in one case as in the other, there is an absence and not an excess of nerve-action. Indeed, M. Charcot himself, while insisting on the "irritating" character of brain-lesions, finds occasion to interpret the effects of certain "lesions," "hemorrhages," and "tumors" as of a paralyzing character. Thus, he finds numerous examples of such cases, implicating the optic bands, the effect of which is to "*paralyze*" the corresponding portions of the retina, producing hemiopia ("Local," p. 98). Another example of a similar kind is to be found in the same work. In referring to destructive lesions indirectly implicating the peduncular fibres of the internal capsule "in consequence of a lesion limited to the gray ganglia which surround the capsule," these ganglia being the corpora striata, thalami, lenticular, and caudated bodies, M. Charcot says: "Thus, the distention of one of these ganglia in case of interstitial hemorrhage might compress the nerve-fibres that compose the internal capsule, and so *suspend their functions*. But, as the nerve-fibres in such cases are only compromised, and not destroyed, *the paralytic phenomena* resulting from that compression (excepting cases of tumor) would always be temporary" (p. 80).

Why is not the same interpretation applied to other lesions of a still more "paralytic," because more "destructive," character?—such, for example, as a copious hemorrhage into the lateral ventricles, in which (usually fatal cases) spasm and rigidity of the muscles are of very frequent occurrence (Bastian), and in which contractions set in early (Charcot). Here, of course, the corpora striata and thalami, occupying as they do the floor of these ventricles, are both, as well as the other adjacent gray ganglia, more or less seriously compressed and damaged. Here, surely, there is ample occasion for the display of "paralytic phenomena;" and it is safe to say that the idea of an excitation of nerve-centres so conditioned is solely due to the exigency of the theory of the day, which demands increased "nervous discharges" in order to account for the muscular contractions, which it has been supposed could not occur in the absence of such a "stimulus"—a supposition to which accumulated facts give a decided negative.

Again, in acute, chronic, and tubercular inflammation, and in hemorrhage of the meninges of the brain, we have twitchings, convulsions, and contractions of the muscles. Have we not here, in the effusion of blood, serum, or pus, pressing on the psychomotor centres and damaging or destroying the medullary fibres, a sufficient cause for "the suspension of their function" by these several parts, and the consequent absence of nerve-force, which has been elsewhere shown to be a condition most favorable for the free exercise by the muscles of their innate property of contractility? The same considerations apply to suppurative encephalitis, with its purulent collections and disintegration of brain-tissue, and the tonic or clonic spasms which accompany that disease.

Diffused cerebral sclerosis is attended by marked flexions of limbs and other distortions from rigidly contracted muscles. We have here "a condition which essentially consists of *a disappearance of that part of the brain-tissue capable of producing or transmitting nerve-force*, and the substitution of another histological element which is of secondary importance" (Dr. W. A. Hammond: "Dis. Nerv. Syst.," p. 275). Under these conditions is it not plainly to an absence of nervous action, and not to an excess of such action, that we must look as the cause of the spasm and contraction referred to? Surely, if violence is not to be done to physiological principles and to the legitimate deductions to be drawn from pathological conditions, this conclusion is inevitable.

Let us now glance at lesions affecting the spinal cord. Consecutive or secondary sclerosis, the result of primary brain-lesion, especially implicates the lateral white fasciculi. M. Charcot, in drawing a parallel between this and primitive spinal sclerosis, writes: "We have established, in an anatomical point of view, that there exists a very considerable analogy between primitive and consecutive forms of lateral sclerosis; that assimilation can be followed upon the clinical field. It is known, indeed, that *motor loss, contraction of the limbs*, at first transient, then permanent, with spontaneous or provoked trepidation, provide a symptomatic group which reveals during life the existence of primitive fascicular spinal sclerosis that is independent of any cerebral lesion. Now, all the essential characters of these symptoms are reproduced in sclerosis arising from a lesion in the brain—the clinical picture, in fact, of common permanent hemiplegia. It may be said, then, that *there exists a relation between the phenomena of 'permanent contraction' and 'lateral sclerosis,' the physiological reason for which at present completely eludes us*" ("Local. in Brain Dis.," p. 129). (Italics mine.)

This is a remarkable admission, and reveals at once the failure of the theory of the day to account for the relations of nerve and muscle. Nor is the extract a garbled one, for the context has been fully quoted. Now, if M. Charcot will accept a hint from an obscure quarter, and recognize the fact that contractility is an inherent property of the muscle; that the muscle needs no stimulus from the nervous system to enable it to contract; that, on the contrary, the *rôle* of the nervous force is to restrain, or inhibit, muscular contractile power, he will find the missing "physiological reason" at once apparent. "The power to generate or to transmit nerve-force" in the cord is at an end, owing to the atrophy, degeneration, and destruction of nerve-tissue; and nerve-force being consequently absent, the muscles are no longer normally restrained, and pass into temporary or permanent contraction in proportion to their freedom.

M. Charcot, however, seems to have felt the necessity of offering some hypothesis in solution of the "relation" between lateral sclerosis and the late contractions of muscles. Accordingly, after disavowing Dr. Todd's hypothesis as to these contractions having their source in "retraction of the cerebral cicatrices," and that of "very many authors" who have referred the cause to "encephalitis supervening in proximity to the lesion," he states as his own "opinion" that "it is *more reasonable* to attribute it to a chronic myelitis in the lateral fasciculus resulting from the cerebral lesion." He refers to Bouchard for "all the proofs that can be adduced in favor" of this opinion. Now if M. Charcot were himself satisfied with these "proofs," why should he have implicitly stated in the next preceding paragraph that "the physiological reason" explanatory of this state "at present completely eludes us?" It is evident that he perceived here "a missing link," and was conscious that neither the opinion he expresses, nor the arguments which could be advanced in its favor, were satisfactory.

Let us glance for a moment at this sclerosis of the lateral white fasciculi of the cord, which has "a relation" to abnormal muscular contraction. M. Charcot, in his "Lectures on Diseases of the Nervous System," describes the process very elaborately. It consists essentially in degeneration of the nerve-fibres, which results in their disintegration and atrophy—a result which is accelerated by the contemporaneous excessive proliferation of the reticulum of connective tissue or neuroglia surrounding and interlacing the nerve-tubules, which, in the words of M. Charcot, are "compressed on all sides, and strangulated." There is a substitution of connective tissue for the proper nerve-tissue, and even where the axis-cylinders persist for a time, they become attenuated and shrunken (Charcot).

These results are so nearly identical with what takes place in myelitis proper, that for brevity the two conditions may as well be discussed together. Dr. Hammond says of the latter: "Microscopical examination shows the existence of congestion, and, as an essential feature, an increase in the amount of connective tissue or neuroglia of the cord. The evidences of this hypertrophy are seen in the increase of fusiform cells and in the production of multinuclear cells and free nuclei. These formations take place at the expense of the proper nerve-tissue of the cord, the anatomical elements of which undergo atrophy and degeneration. The nervous tubules are thus often disintegrated and their contents disseminated through the extraneous tissue. The axis-cylinders are entirely surrounded by oil-globules, or are altogether broken up and rendered unrecognizable. . . . . When the lesion is in the gray substance, the microscope shows the nervous cells to be broken up, etc." (p. 461). Even in the chronic form of myelitis (as in sclerosis), the changes are still "characteristic of hypertrophy of the neuroglia *at the expense of the proper nervous tissue*" (Ib.). Is it not apparent that nerve-tubes so conditioned are utterly incapable of transmitting their proper motor impulse, and that, so far as they are concerned, their relation to the muscles is that of an absence of nerve-action?

Those who are resolved on finding a source for a stimulus to the muscle, may urge that the motor cells of the anterior gray cornua are irritated and excited by the sclerotic process taking place in the contiguous lateral fasciculi, which pass down the cord in near proximity to the anterior cornua, and have terminal fibres in the latter; and that to such an irritation and excitation of the motor cells of these anterior gray cornua, the spasmodic contraction of the muscles is to be attributed.

The following considerations may be urged in reply:

1. Such a view is inconsistent with the history and course of the disease, which begins in the most important motor tracts of the brain as "a destructive lesion—that is, one capable of interrupting the course of the medullary fibres" (Charcot, "Local.," p. 124), and thence extends into the cord, producing atrophy and arrest of function as it descends. Consistency requires that it should exercise a similar injurious influence over the terminal motor cells, depriving them of their functional activity rather than exalting it.

2. According to Weber, as quoted by Prof. Kuss, "thirty excitations a second are usually required" on the part of a nerve-centre to produce continuous contractions of muscle. Now, the hypothetical excitation of the motor cells of the anterior cornua, under the conditions shown to exist, would surely be inadequate to maintain such a rate of nervous discharges, often during long periods of time.

3. Even were *increased morbid action* shown to be present in these motor cells, this would not imply *augmented functional activity*. A splinter under the nail produces increased morbid action, but it is attended by loss of tactile sensibility. A diseased eye, from sympathetic irritation, displays increased morbid action, but proportionate loss of vision. A too rapidly beating heart, in asthenic cases, has, with the appearance of increased action, lowered functional power, and only accomplishes at two beats what it ought to effect with one. It is needless to multiply examples. Even in the highest forms of irritation—inflammation—our leading English authority, Dr. W. B. Carpenter, assures us there is a *lowering of function*, and it has never been asserted that nerve-tissue furnishes an exception to the rule. This fact supplies an insuperable objection to the hypothesis that during myelitis the nerve-centres are discharging increased nerve-force, and in consequence stimulating the muscles to contract.

4. The objection is further fully met by the fact that abnormal muscular contractions, both transient and permanent, are found present in cases where the motor-cells of the anterior gray cornua are atrophied and destroyed. Cases of this kind have been reported by MM. Charcot and Joffrey, typical examples of which are quoted by Drs. Hammond and Bastian in the works referred to above. The same motor-cells undergo a destructive process in progressive muscular atrophy; in every one of the twenty-nine cases of which, observed by Dr. Hammond, fibrillary contractions were present "in the paretic muscles." A similar degeneration of the cells of the anterior gray cornua occurs in infantile spinal paralysis, which is "similar in several respects to progressive muscular atrophy," and in which "contractions and distortions are much more common" (Hammond). The occurrence of muscular spasm and rigidity during the atrophy, disintegration, and destruction of the motor-cells of

the gray cornua themselves is sufficient proof that the abnormal muscular contraction in question is not due to an irritation or excitation transmitted to these cells as a result of the contiguous lateral sclerosis, which is the view of the case now under discussion.

5. Lastly, any such hypothetical irritation or excitation of the gray substance of the cord is inconsistent with the fact here stated on the authority of Dr. Brown-Séquard, that, like the nerve-fibres of the cerebral lobes, "the gray matter of the cord" is not excitable, and "when irritated it does not transmit anything, because it is not itself impressible" ("Lectures Cent. Nerv. Syst.," pp. 18, 134).

Dr. W. A. Hammond offers his readers a singular illustration of the inconsequence of the theory of the day in this connection, which may not be passed over in silence. "Several authors," he says, "have laid great stress on the occurrence of violent tonic contractions of the limbs" in sclerosis of the antero-lateral (or motor) fasciculi. Dr. H. will not admit this very natural view of the case, but charges the said contractions to "the meningitis which is often an attendant condition" ("Dis. Nerv. Sys.," p. 482). Now, the meninges of the brain do not generate nerve-force, even when inflamed; and as the effect of sclerosis, according to the same author, is such that "the cord loses both the ability to transmit or to generate nerve-force," it is difficult to see from whence can be derived the extra stimulus to urge the muscles to "violent" contractions. The "physiological reason" for such "a relation" between the cord and the muscles most certainly "completely eludes us."

In his "Lectures on the Diseases of the Nervous System" (Sigerson: Lea, Phil., 1879) M. Charcot defines the phrase "irritative lesions" to mean "lesions which determine in the nerves or nervous centres an exaltation of their properties, an irritation, or an inflammation" (p. 9). These lesions give rise to a variety of peripheral nutritive disturbances, for example: in the skin, to herpes, bullæ, and bed-sores; in the viscera, to ecchymoses; in the joints, to rheumatoid affections; in the muscles, to paralysis, spasm, and rigidity, and more rarely to muscular atrophy and degeneration.

It has been attempted in the foregoing paragraphs to show that the character of these lesions is quite incompatible with their being the occasion of an exaltation of nervous function; and M. Charcot himself furnishes additional evidence that the peripheral effects of these central lesions are of an adynamic, ataxic, and paralyzing type. He shows "that in a considerable number of cases, at least"—and he mentions among them partial myelitis (pp. 92, 93)—there is an absence of hyperæmia and of increased temperature, both of which accompany and characterize tissue-changes of an active kind. Indeed, he withdraws these peripheral nutritive disturbances altogether from the influence of the vascular system, declining to follow "the wanderings," or to be bound by "the inanity" of the vaso-motor theory at present in vogue (pp. 36–90). He finds that "congestive and ecchymotic lesions form a separate order" (p. 86)—the latter being the peripheral tissue-change affecting the viscera. In nephritis and cystitis, which "are very common complications of irritative spinal affections," he finds symptoms and conditions, parallel to those resulting from "traumatic paraplegia," occurring during "spontaneous acute myelitis and in hematomyelia," conjointly with eschars on the sacral region and a diminution of electrical contractility "in the paralyzed muscles" (pp. 87, 88). These, as well as other peripheral morbid changes, M. Charcot attributes to the "direct action of the nervous system," exerted through the agency of the sensory and motor nerves, in both of which he claims impressions produced at any point "are propagated at once and simultaneously in centripetal and centrifugal directions" (pp. 89–103).

Such an exposition of the mode of production of peripheral nutritive disorders of a consecutive kind, by direct nerve-influence, without the intervention of the vascular system, and occurring, too, in numerous instances, in the absence of hyperæmia, while "the skin is generally pale and bloodless, and at the same time the local temperature is manifestly lowered from the very beginning" (p. 36), can hardly be regarded as implying other than defective, rather than exalted, vital action.

It is in singular contrast to the alleged "exaltation" of nerve-function that we find associated with this such phrases as "fatal irritation in *paraplegia;*" and the introduction of a quotation from Dr. R. Bright, in which, while discussing spinal lesions, it is suggested that "the connection between *interrupted nervous action* and the formation of bullæ" might be found to throw some light on the nature of herpes zoster" (note, p. 59). Since both the bullæ and the herpes are among the peripheral changes elsewhere attributed to exaltation of nerve-force, the words "interrupted nerve-action" are not without significance in such a connection.

Again, infantile spinal paralysis is said by M. Charcot to be "the most perfect type of the affections which compose" one of these groups of central "irritative" lesions. He states: there is here "a profound alteration of a large number of motor-cells in the region of the cord whence the nerves emanate which supply the paralyzed muscles. In the vicinity of the atrophied cells the connective network almost always offers manifest traces of an inflammatory process. Judging from the general aspect of the phenomena, we are induced to admit, as a highly probable hypothesis, that in infantile paralysis a *superactive irritative action* suddenly seizes on a large number of nerve-cells and *makes them promptly lose their motor functions*" (p. 47). Surely M. Charcot does not seriously regard such a result as due to "an exaltation of the properties" or functions of the motor-cells referred to, when the condition of the nervous centres and his own naïve admissions as to "loss" and "interruption" of nervous action point unmistakably to paralysis and the absence of the proper influence of the nervous system. Besides the "paralysis," spasms and contractions resulting in muscular distortions are also among the results of this condition, and are fairly attributable to the same cause—loss of motor-nerve action, occurring in varying degrees of intensity; "paralysis" being the result of a separation of the muscle from the influence of the will, and spasm and rigidity ensuing when the nervous filaments in the muscle are dead, down to their finest ramifications and motorial end-plates, so that the molecular state of the ultimate nerve-fibrils ceases to inhibit the ultimate fasciculi of the muscle. When this occurs, the muscle passes into a state of rigidity, which, when it is present during life, is simply the counterpart and anticipation of *rigor mortis.* When this rigidity gives place to relaxation, in exceptional cases, the nervous centres have either in part regained control over the muscles, or, owing to atrophy and degeneration of structure, the muscle has lost its property of contractility.

Especial reference has here been made to M. Charcot's valuable expositions, in order to show that authentic clinical facts tend strongly to confirm the conclusion arrived at by Dr. C. B. Radcliffe and others, as the result of physiological experimentation, that muscular contraction takes place to the best advantage in the absence of the influence of the nervous centres. It is believed that the facts here adduced tend also to establish that the latest and highest authorities are (involuntary) witnesses to the truth of the theory advocated in the antecedent articles in the RECORD, "on the relations of nerve and muscle."

THE SUBCUTANEOUS USE OF HYDROBROMIDE OF CINCHONIDIA IN THE SUMMER DIARRHŒA OF CHILDREN.

By S. HENRY DESSAU, M.D.,

PHYSICIAN TO THE OUT-DOOR DEPARTMENT OF THE NEW YORK FOUNDLING ASYLUM.

A CONTINUED high temperature, in conjunction with a low barometric pressure during the summer months, is certainly the most important factor in the causation of a rapidly fatal form of diarrhœa in children in this country. A study of the statistics of infantile mortality from diarrhœal complaints during the hot season, in our large cities, together with close observation of the disease, has led pediatricians to adopt this view.

The direct effect of excessive heat and low barometric pressure upon the infantile nervous organization is analogous to the insolation and heat fever produced by the same causes in the adult. In the former, however, the pathological action is expended upon the intestinal tract. It is not denied that other elements, such as putrefactive fermentation, foul air, and improper food, are also prominent aids in the causation of summer diarrhœas in children, but in that form accompanied with hyperpyrexia and severe and rapid prostration of the vital forces, these latter factors take only a secondary rank in importance.

It is in reference to this form, or the cholera infantum, as it has been commonly called, that I wish to bring to the attention of the profession the subcutaneous injection of hydrobromide of cinchonidia, as a powerful means of assisting in reducing temperature and restoring the vital forces. I was led to employ this method of treatment after reading a report of the successful treatment of cases of heat apoplexy, or sunstroke, by the subcutaneous injection of quinine by Surgeon A. R. Hall, of the British Army (*The Practitioner*, March, 1876, p. 196). Recognizing the similarity of cause that existed between sunstroke and this particular form of summer diarrhœa in children, it occurred to me that the same treatment might answer a like useful purpose in the latter trouble. Instead of using quinine, which frequently produces abscesses when hypodermically injected, I substituted a solution of hydrobromide of cinchonidia, as a more concentrated and harmless preparation, on the authority of Prof. Gubler (*Journal de thérap.*, No. 1., 1879), who states that three grains of hydrobromide of cinchonidia, subcutaneously administered twice daily, has the same effect as fifteen to thirty grains of quinine taken by the mouth. The hypodermic method of using the remedy is advantageous in avoiding the vomiting incident to the intestinal diseases of children, thus securing a speedy action of the remedy without disturbing the already hypersensitive stomach. After vomiting has ceased, however, the good effects of the remedy may be maintained by administering it by the mouth.

I subjoin the following cases to illustrate the effect of the treatment. They have been copied from the register of the Out-door Department of the New York Foundling Asylum.

CASE I.—June 14, 1879. Adele, two months old; bowels loose for two days; passages expelled with force in a stream, are watery and yellow, very frequent; vomits, moans, and contracts the brows. Temperature, 103⅕° F. in rectum. Injected about one grain of hydrobromide of cinchonidia over nates, subcutaneously. Gave hydrarg. c. cret., tr. opii deod. and bismuth subnit. in a mixture every three hours; ordered hot baths and fomentations to abdomen.

July 1st.—Nurse reported that the child had a convulsion on June 15th. The bowels improved the second day after last note and are now regular.

This case is reported because it was the first one in which I used the hydrobromide of cinchonidia hypodermically. The temperature was not so very high, and the same result would most likely have occurred with the other part of the treatment alone.

CASE II.—June 28, 1879. Robt. Woods, one year old; bowels became loose, thin and yellow, the same morning, about five o'clock; no vomiting; bowels moved frequently. Temperature, 105 F. in rectum. Injected ¾ gr. hydrobromide cinchonidia, hypodermically over nates. Gave a mixture of carbolic acid gtt. ¼, tr. opii deod., gtt. ⅜ and mist. cret. ʒ j. every two hours.

Died the next day. The negative result in this case was due, in a great measure, to the local surroundings and improper care in executing medical instructions on the part of the nurse.

CASE III.—June 28, 1879. Willie, five months old; diarrhœa for four days; convalescent from an attack of croupous pneumonia. Looks very pale and depressed by the heat; is very thirsty. Temperature, 104° F. in rectum. Four passages a day, dark brown and thin; no vomiting. Gave ¾ gr. hydrobrom. cinchonid. hypoderm., injection over nates. Gave mixture of hydrarg. c. cret., tr. opii deod. and bis. subnit. every three hours. Ordered cold baths every three hours.

July 1st.—Bowels moved only twice since last note, thin and yellow. Had two cold baths. Temperature to-day, 99⅗° F. in rectum. Nurse reported that he began to improve immediately after the hypodermic injection. Bowels remained loose for awhile, but were finally checked.

CASE IV.—July 15, 1879. Arthur, seven months old; no teeth; sick twenty-four hours; diarrhœa and vomiting; twenty passages so far, yellow and watery; refuses the breast. Temperature, 105⅗° F. in rectum. Gave hypodermic injection of ¾ gr. hydrobrom. cinchonid. over nates. Ac. carbolic, tr. opii deod. and mist. cret., every two hours; cold bath every three hours; brandy and toast-water as a drink.

July 17th.—Slept to-day for the first time in two days; bowels not moved since last night; is very restless now, tossing the head from side to side and screams out suddenly at intervals; pupils contracted. Temperature, 102⅗° F. in rectum. Repeated the hypoderm. injection ot cinchonid. and gave a mixture of ferri et ammon. tart. and tr. opii. camph. every three hours. Ordered applications of cloths wet in hot water to be made to the head.

July 19th.—Sleeps well; two passages from bowels since last note, were thick and black. Temperature, 99⅖° F. in rectum.

Case V.—July 15, 1879. Thomas, two months old, has diarrhœa; looks very sick; passages from bowels green and slimy, very large in quantity. Temperature, 106⅘° F. in rectum. Injected ¾ gr. hydrobromid. cinchonid. into nates; gave a mixture of hydrarg. c. cret., tr. opii deod. and bis. subnit. every three hours; ordered cold baths, brandy and toast-water as a drink. Died the next day.

As life was undoubtedly prolonged in this case by the reduction of temperature, induced by the hydrobromide of cinchonidia, it is reasonable to suppose that, had the injection been repeated, the slight improvement gained might have been increased and a successful result secured.

Case VI.—July 29th. John James, nineteen months old, began vomiting the day before, at 4 o'clock p.m., followed by diarrhœa; passages yellow and watery. Temperature, 103⅕° F. in rectum. Injected ¾ gr. hydrobrom. cinchonid., subcutaneously, over nates; gave a mixture of carbolic acid, tr. opii deod. and mist. cret. every three hours; ordered cold baths, brandy and toast-water as drink.

Aug. 6th.—Bowels now moved three times a day; passages thick and yellow. Temperature, 100° F. in rectum.

Case VII.—July 29th. John, two months old, has diarrhœa and vomiting one day; looks sick; passages green and watery; vomits greenish fluid. Temperature, 104⅗° F. in rectum. ¾ gr. hydrobrom. cinchonid., subcutaneously, over nates; ac. carbolic, tr. opii deod. and mist. cret. every two hours; cold baths, brandy and toast-water.

Aug. 5th.—Bowels improved; vomiting checked; has now thrush and some cough. Temperature, 102⅘° F. in rectum. Gave the hydrobromid. cinchonid. one grain four times daily, by the mouth. Afterward did well.

Remarks.—The result of the method of treatment as above described, though, perhaps, not as brilliant as could be wished for, is nevertheless highly satisfactory to one having a large experience in the summer diarrhœas of children. In both fatal cases, the temperature was 105° F. and 106⅘° F., respectively, and the general prostration severe. In the remainder, the temperature was never below 103° F., and in the case showing the most brilliant result, it was 105⅗° F. It may be said that as much credit was due to that part of the treatment outside of the hypodermic injections of hydrobrom. cinchonidia as to the latter. Be this as it may, I feel satisfied that, unless the temperature can be reduced and the prostration of the nervous centres restored promptly in the severer form of summer diarrhœa in children, that there will not be much time left to allow other remedies to exert any effect. Especially is this view all the more correct, if, as Binz has stated, in explaining the antipyretic action of quinia in sunstroke, the overpowering effect of excessive heat upon the nerve-centres is due to a poisoning of them, through a decomposition of the nutritive material of the blood. Quinine, according to Binz, who is perhaps the highest authority upon the therapeutical action of this remedy, even in relatively small quantities, acts directly upon the protoplasm, and prevents any putrefaction of nitrogenous substances. It even neutralizes the poisonous action of many putrid fluids upon warm-blooded animals, as far as certain symptoms are concerned, and checks activity of cells, decreasing the oxidation and disintegration of the tissues.

Unfortunately the injections in the cases reported could not be repeated as often as they should have been, which would be at least once, if not twice, in the twenty-four hours. Binz states that quinia remains in the circulation for many hours, and when given once a day in not too small a dose, circulates through the tissues, keeping them constantly under its influence. In future cases, I intend to use not less than one grain of the hydrobromide of cinchonidia, hypodermically, at one dose, where there is no opportunity to repeat the injection daily. This, it must be remembered, is a full dose for an infant. I use a ten per cent. solution, giving eight minims at an injection.

75 West Fifty-fifth Street.

Reports of Hospitals.

BELLEVUE HOSPITAL.

Notes of Practice and Items of Treatment.

DYSENTERY—SUDDEN DEVELOPMENT OF PERITONITIS.

The patient, a female, æt. 38, who gave the following history, had just entered the hospital. Her case was interesting chiefly with reference to diagnosis. She had had dysentery for six months, but which had not interfered with her to such an extent as to prevent her from performing nearly her usual amount of work. The dysentery came on, gradually grew worse, the passages getting more and more frequent, until she had a large number, 20 to 30, in the course of twenty-four hours, and she was positive that the discharges contained mucus and pus. She had had a slimy, bloody discharge since admission to the hospital. Three days ago an entirely new set of symptoms was developed. She was seized with a different kind of pain in the abdomen, and for the first time noticed that her abdomen was swollen. She then began to vomit, and the vomiting had continued, the swelling of the abdomen had increased, and she had steadily grown worse. Her temperature was 100¾° F.; pulse, quick and rather hard, 132. She had had chilly sensations, but no distinct chill. There was nothing specially noticeable about the countenance. Her respiration was frequent, and mostly thoracic. The limbs were not flexed upon the trunk. The abdomen was tympanitic and generally tender. There was no sensation of fluctuation. The pain was most severe upon the left side, along the course of the colon. A murmur was heard with the first sound of the heart, at its base, and with greatest intensity along the course of the vessels in the neck. Area of cardiac dulness was normal; and apex was in normal position. Pleuritic friction-sounds at lower portion of right side of the chest anteriorly, probably not of very recent origin. Neither the clinical history nor the physical signs sustained the suggestion that it might be intestinal trouble dependent on pulmonary disease. The vomiting was rather characteristic of peritonitis; being for the most part of a regurgitation of greenish fluid. The characteristic spinach vomiting of peritonitis does not occur as a prominent symptom in peritonitis until the inflammation has reached that portion of the serous membrane covering the stomach. It was believed that her recent disease was a localized peritonitis from ulceration somewhere along the course of the descending colon, and from that point it had become general. Prognosis was grave, though not necessarily fatal. The treatment was opium in full doses, so as to bring the patient into a semi-narcotized condition as rapidly as possible, consistent with safety. But suppose the pulse did not fall below 120, or the respiration below 17, and yet it was with difficulty that the patient could be aroused, would it be judicious to still push the opium? The answer was that there are patients upon whom opium acts badly, and that the physician was obliged to feel his way carefully. Under such circumstances it was thought proper to administer veratrum viride to assist in reducing the pulse. Milk and lime water was ordered for food. Objection was made to using leeches on account of the patient's anæmic condition. Hot applications were made to the abdomen.

MALARIAL FEVER OF THE REMITTENT TYPE—DEVELOPMENT OF CONSOLIDATION AT THE APEX OF THE RIGHT LUNG.

The following case was especially interesting with reference to the rapid development of pulmonary consolidation. The diagnosis, when the patient first came into the hospital, was remittent malarial fever, and the jaundice, which was marked, was supposed to be the result of changes produced by the fever, with, perhaps, slight catarrh of the hepatic ducts. At first his temperature was 104° F.; it ranged between 104° and 103° F. for several days, and finally fell to 100° F. On the day following that on which the temperature fell to 100° F., it rose to 103° F.; in the morning of the next day was 100° F., and in the afternoon 103° F. There were regular exacerbations and remissions. His temperature, at the time this note was made, was 100° F., and had fluctuated between 100°, 101°, and 102° F. for several days. Within two weeks the physical signs of consolidation at the apex of the right lung had developed, and the question arose, was phthisis developing? There was physical evidence of pulmonary consolidation, both anteriorly and posteriorly, and the signs did not appear until the fever had rather spent its force, and they had increased somewhat. Although his general condition seemed to be improving, it was believed that it was a case of a low type of catarrhal pneumonia in which resolution would probably occur, and recovery. The case was interesting as showing that when patients were in a broken down condition, from any cause, pulmonary consolidation might be developed at the apex of one or other of the lungs, and give the physical signs of phthisis. Not infrequently, such cases terminated as fully developed phthisis; yet, while they were not promising, it was remarked, recovery in a large proportion took place, even if the physical signs were quite positive.

EMPYEMA—SPONTANEOUS OPENING—IMPORTANCE OF EARLY ASPIRATION.

Two cases were seen in contrast. The history of the *first* was as follows:

April 28th. A male patient had been sick since the second day of January, when he had what his physician called pneumonia. He was out on the first day of January, and on the next day was taken with pain in the left side, without chill, had a cough, and expectorated a white phlegm, which, during the first week, was scarcely streaked with blood, but subsequently was so markedly. He had some fever, and was confined to his bed during the entire month of January.

Subsequently a bunch appeared in his side, which broke and discharged a large quantity of yellowish fluid, and the discharge had continued up to date. The opening was about two inches below the left nipple. He could sleep only when lying upon his back.

The history of the *second* case was as follows: A male patient had been sick since last September, when he was taken with pain in the left side, without chill and without cough, which continued two weeks. He could sleep only when lying upon the left side. He had lost flesh, and latterly had had night-sweats.

Physical examination in the *first* case made the diagnosis very clear, and it was, that the patient had empyema, with spontaneous opening. The opening was rather lower than usually occurs in spontaneous thoracentesis, which may be behind or in front, but in the majority of cases at the latter point. The heart was pushed over to the right side considerably. The left side was retracted.

Physical examination in the *second* case revealed that the left side was enlarged; upon full inspiration there was loss of motion; there was entire absence of all respiratory sounds, and there was complete flatness on percussion. The heart was pushed over to the right so that the apex-beat was found a little beneath the right nipple. There was bulging of the intercostal spaces. For a few days he had night-sweats. Pulse 134. The left pleural cavity was completely filled with fluid.

The two cases illustrated two conditions or stages in the same disease. In both cases was shown, in a striking manner, a change in the position of the heart.

In one case the spontaneous opening occurred early; but why in some cases such opening occurred early while in others it occurred very late, was not well understood, yet it had been noticed that the younger the subject the more likely was spontaneous opening to occur early; whereas in the older subject it occurred late, if at all. In some cases, also, the general process is slower than in others. It was believed that if the fluid had been drawn from the chest in December or January, in the second case, the patient would have been nearly well, perhaps entirely so; and the case illustrated the importance of removing the fluid from the pleural cavity early in its history, with a view to preventing a change of the product of the inflammation into a purulent collection.

With so much displacement of viscera as was manifested in the second case, it was believed to be important to remove a portion of the fluid from the pleural cavity promptly, as the man was in constant danger, if unrelieved, of sudden syncope, from which he might not rally.

A Costly Fossil.—Those who in their college days knew, and more or less loved, that interesting fossil, the archæopteryx, will be pleased to learn that the finest specimen in the world has just been purchased for the University of Berlin. The sum paid was $20,000, which seems trifling when we consider how few archæopteryces there are in the world, and how many wealthy people. It may be remembered, but more probably will not, that the archæopteryx sang and flew during the Jurassic period, of which it has been considered the nightingale, by those who think the creature a bird. Those who think that it is a reptile, deny it, of course, that title. We hope that the question as to which it is, will be decided soon by the authorities at Berlin. There are hundreds of liberally educated young men who every year leave college without any well-defined idea on the subject. Yet the market price of the archæopteryx ranges from $10,000 to $20,000.

Progress of Medical Science.

On Persistent Priapism not Connected with Lesion of the Central Nervous System.—A very interesting case of priapism, probably due to a leucocythemic condition of the blood, is narrated by Dr. G. L. Peabody, of this city. The patient, a coachman, twenty-eight years of age, had had fever and ague in 1874, and again in February, 1879, when he also suffered from epistaxis. When first seen by Dr. Peabody, he complained of priapism, which was unaccompanied by seminal emissions, or sexual desires. He could urinate without difficulty, as the erection was only confined to the corpora cavernosa. His kidneys were affected, as was shown by the general anæmic condition, the swelling of the feet, and the presence of albumen and hyaline casts in the urine. The spleen was enlarged, as were the cervical and inguinal glands. As he suffered from great pain in the perineum, when he attempted to sit down, he was kept in the recumbent position, and his penis protected from the bedclothes. Quinine, and later cinchonidia, was given internally, and ergot injected hypodermically over the site of the spleen. At the end of a month his penis was of the usual size, and during this time the temperature often rose to 101° F. in the evening to fall to 99° F. the next morning. The blood was examined and found to contain white corpuscles in large quantities, being in the proportion of one white to two, three, four, or six of red blood-cells. He still had epistaxis, but his health had improved under the internal administration of iron. The spleen continued of the same size, and there were imperfect erections of the penis. Iodide of potassium, given internally, together with the local application of tincture of iodine, failed to prevent the increase in size of the glands. In the beginning of the year (1880) he was in the same condition. This is said to be the seventh case on record, where priapism occurred in a leucocythemic patient.—*N. Y. Med. Journ.*, May, 1880.

Periarthritis—A Study of Forty-seven Cases.—Dr. Gibney, of this city, employs the above term to designate an inflammation of the loose cellular tissue surrounding the different articulations. He says that the object of the paper is to popularize the name and to show that it is a more common affection than is generally supposed. It differs materially from diseases of the joints, whether primary or secondary. The symptoms are generally acute, there being pain, heat, and infiltration, and, if in a late stage, there is fluctuation about the joint, which may end in suppuration. Of the forty-seven cases on which the article is based, the average length of time from the commencement of the disease, or when the pain was first noticed, until the limb was restored to its natural condition, was from five to six months. Ten of the patients were cured in one month from the time of the first pain, thirty in four months, and in one the disease lasted three years, although the joint was not involved. Suppuration took place in thirty-five of those affected, in the following localities: 18 at the hip-joint; 8 at the knee; 4 about the ankle; 3 in the vicinity of the sacro-iliac articulation, and 2 over the spine. The disease existed at the hip-joint in 20 of the cases; at the knee in 18 patients; near the ankle in 4 instances, the sacro-iliac joint was involved in 3 cases, and the remaining 2 had their spine affected. The ages of the patients were as follows: 3 under one year; 26 under four years; and 2 over seventeen, the oldest being fifty-seven years of age. The ages of the remainder are not given. There were 28 males and 19 females affected. In 7 instances the disease was caused by a fall; 2 produced by a strain; 2 by vaccination; 1 each by rubeola, hereditary syphilis, and thrombosis; in 33 there was no ascertainable cause. The prognosis is good, both in reference to recovery and a complete restoration of the functions of the limb involved.—*N. Y. Med. Jour.*, May, 1880.

Erysipelas Affecting Successively the Pharynx, Mouth, Breast, Face, and Lungs.—M. Luc reports this remarkable case, which was observed at La Salpêtrière, service of Dr. Terrier. The patient, eighty-three years old, was first seen on the 18th of February, presenting then the following appearance: tongue considerably swollen; could scarcely be extruded; buccal mucous membrane intensely red, swollen, and offering a characteristic glazed aspect; painful swellings about the submaxillary and retromaxillary regions; isthmus faucium same color, but less swollen; marked difficulty of speech and deglutition, embarrassed respiration, but heart and lungs normal. Sternal region shows erysipelatous redness. The disease was ascertained to have set in with repeated initial chills, followed by violent throatache and vomiting of biliary matter. The patient improved, under appropriate treatment, until the 21st of February. At that time she again grew worse; there was a marked febrile movement, and physical examination now revealed a pneumonia of the lower third of the left lung. In a few days the patient rallied, and finally completely recovered. The author also alludes to two similar cases. One was observed by M. Stackler. A young woman was attacked by an erysipelatous inflammation proceeding from the pharynx to the face and back, and finally producing pneumonia of the right lung. The other came under the notice of M. Straus, and related to a man who died of erysipelatous pneumonia. At the autopsy characteristic redness and swelling were still found on the surface of the tracheal mucous membrane and in the bronchi of one lung.—*La France Médicale*, March 31, 1880.

On the Partial Metabolism by the Liver of Leucin and Tyrosin into Urea.—As a result of the examination of the urine of several patients affected with various diseases, such as emphysema, Bright's disease, hemiplegia, etc., Dr. Edward C. Anderson has been able to determine the presence of leucin and tyrosin, either separately or together, accompanied by a relative diminution in the quantity of urea excreted from the kidneys. Tyrosin was found to be absent in nineteen out of the thirty-three cases, contrary to the prevalent opinion, which is, that leucin and tyrosin are generally found together. As the leucin disappeared from the urine, the urea increased in quantity. He believes that the leucin and tyrosin take the place of the urea. In cases where there is increased formation of urea, together with the formation of leucin and tyrosin, it is produced by the great destructive metabolism, which is shown by the fact that as convalescence progresses, although the amount of urea excreted has diminished, there is also a diminution of the leucin and tyrosin and a final disappearance of them. This transformation of urea into leucin and tyrosin is well shown in acute yellow atrophy of the liver.—*Lancet*, April 17, 1880.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, July 3, 1880.

THE NIGHT MEDICAL SERVICE.

The bill for the creation of a night medical service having passed the legislature, and having been signed by the governor, has now become a law which will soon be put to a practical test. It will be remembered that, several months since, Dr. Henri Nachtel, of Paris, read a paper before the Academy of Medicine, giving a detailed account of the workings of the system of night medical service in his native city, and urging its adoption in New York. Although, from what we had already learned concerning the benefits of the system in Paris and other cities in which the service had been tested, there was little doubt that New York could, by the same means, be likewise benefited. Dr. Nachtel's paper drew renewed attention to the subject, and gave a thoroughly practical turn to the whole matter. After the favorable reception of the paper by the Academy of Medicine, and by the profession generally, in this city, a bill was prepared, in which the system of service in Paris was adapted to the wants of this city.

At the time of the presentation of the bill we gave a synopsis of its provisions, and took occasion to urge its passage. As might have been expected, there was some show of political opposition in the legislature, but the bill finally passed by a large majority, and then came before the governor for his signature. Here the greatest difficulties appeared to present themselves. The heads of departments were to be consulted, and not until an influential representative from each was ready with his endorsement, did the governor take upon himself the responsibility of affixing his signature to the document. Considering the small amount of money (three thousand dollars) required as an appropriation for carrying out the provisions of the law, it is somewhat remarkable that any opposition whatsoever should have been offered. If any reflection, from a political standpoint, is to be cast upon the real merits of the law, it is that so much good service can be rendered the public by such a small outlay of money.

As will be remembered, the bill, which has now become a law, provides, in substance, that there shall be kept at each police station a list of physicians approved by the Health Board, and who shall be ready to respond to night calls, for the sum of three dollars per capita. In case the patient is too poor to pay for the service, a certificate of attendance is issued by the officer having charge of the station, which certificate is duly cashed by the treasurer of the service fund. In order that no partiality may be shown to any practitioner, and that no valuable time may be lost, it is provided that, under all circumstances of emergency, aid shall be obtained from a source as near as possible to the patient.

There has never been a doubt as to the utility of a night medical service in New York, or in any other large city. No objection has ever been urged on that score, even by those who at first opposed the passage of the bill. All the arguments brought to bear against it were centred in the difficulty under the existing form of municipal government of making it effective. As it is, however, its working is simplified by attaching the bureau to the Health Department, where it very properly belongs. By such means the public is guaranteed that none but well-qualified practitioners of medicine will be recognized as volunteers for the service, and none others will have their names upon the official lists. And of no less importance is the fact that prompt attendance is insured to all who may be in emergency. It is fair to presume that there will be no lack of volunteers. In fact there is a chance of having more than is really required; but this will work no harm in any direction.

Taking a purely professional view of the situation the creation of a night medical service is of importance in that it will tend to relieve many practitioners who are unable to respond to night calls, will protect them from being unnecessarily disturbed by chance callers, and will give the younger practitioners a chance to be paid for work which would otherwise be entirely gratuitous with the loss of sleep besides. Again, small as is the appropriation, it is made upon the principle that the public is willing to pay the private physician for services he may render to the needy pauper. It is a recognition on a small scale of the obligation of the municipality to provide for medical services to its poor, in the proper way by paying for them.

As such it may have a significance as a precedent which will overshadow the particular object for which it has been established.

THE SANITARY CONDITION OF MEMPHIS.

The first Annual Report of the Board of Health of the Taxing District of Shelby County, is based, to a considerable extent, upon the sanitary survey of Memphis made last winter by the National Board of Health. The results of this survey were presented some months ago and were referred to at the time in The Record. The report now before us supplements that made to the National Board, and from the two an excellent idea of what is being done for the sanitary improvement of Memphis can be gained.

During the two epidemics of yellow fever in 1878 and 1879 two thousand and seventy-two persons died within the corporate limits of the city of Memphis. This loss, taken with the paralysis of business it occasioned and the extra drain upon the taxpayers, might well be expected to have ruined the once thriving city. It has shown, however, a wonderful elasticity; its present population is now greatly diminished, and, if no epidemic occurs during the present summer, there will undoubtedly be a continuance of its former prosperity. The present Board of Health was organized in February, 1879. It has worked indefatigably ever since and has at last initiated or completed sanitary reforms which promise to make the city a model one. In the beginning, there was scarcely any direction in which some sanitary work was not needed. The streets were covered with decaying pavements, the sewerage was imperfect or absent, the water-closets were holes in the ground and often near the wells and cisterns. There were accumulations of filth in many places. The drinking-water was bad, the schools and other public buildings poorly ventilated and incompletely drained; in fact, Memphis had been going along in a slip-shod kind of way, almost inevitable perhaps to a struggling city with a large colored population.

Work has, however, been begun which will in time remedy nearly all these defects; and as much as could possibly be expected has already been accomplished. A complete system of sewerage and subsoil drainage is now being introduced; coincidently with this, privy vaults are being emptied, disinfected, and filled up. Three thousand of these were in a dangerous condition; and at date of the report over 1,400 had been filled. Earth-closets or water-closets are substituted for them. Of dangerous buildings, 112 have been torn down. Much of the old Nicholson pavement has been taken up and replaced with stone. The use of cisterns and wells containing impure water has been discontinued; all buildings within fifty feet on each side of Bayou Gayoso have been removed. Finally, a thorough system of local sanitation has been introduced; part of this consists in the appointment of a corps of eight inspectors who make daily inspections and report to the Health Office.

The report before us, besides thus detailing the work now being done, gives a history of the epidemic of 1879, and makes recommendations regarding the water-supply, the public schools, and the latrines.

On the whole an encouraging view of the future of Memphis is given. Every one will sympathize in the hopes of prosperity expressed, and will watch with interest the result of the past winter's work upon the pestilential influences of the summer.

THE INCREASED RANGE OF DOSAGE AND THE LAW OF SIMILARS.

No one can fail to have noted the increased therapeutic range which has of late been given to many standard drugs by simply varying their dosage. We have, indeed, had our materia medica enlarged almost as much in this way as by the actual addition of new remedies. This extension has been made both by increasing and by diminishing the ordinary dosage, and in each case new effects have been produced. It is perhaps in calomel, strychnine, and the potash salts that a different or a greater power in very large doses is best illustrated. The employment of minute doses, on the other hand, has been much more extended and has produced more striking results. Thus the use of podophyllin in infantile diarrhœa, of arsenic in gastric irritation, of ipecac as an anti-emetic, of pilocarpin and Dover's powder, and Turkish baths in night-sweats, of cantharides in urethral irritations and hæmaturia, are all notable extensions of the therapeutic range of the particular drug.

Of course, such examples as these are eagerly held up by enthusiasts as proofs of a grand therapeutic law. It hardly needs argument, however, to show that they do not indicate either a law or even a uniform series of facts. There are but few drugs which have even this peculiar range we have described, and these do not, as a rule, show their best results in their minimum doses. We doubt if arsenic ever becomes popular in gastritis, or pilocarpin in night-sweats, while ipecac is a most unreliable anti-emetic. We need not look for any great therapeutic triumphs therefore in the *similia similibus* action of the drop posology. There is a physiological law that substances which at first irritate inhibitory centres, when more energetically given, will paralyze them; or what at first constringes a tissue, may, later, relax and destroy it. There is nothing very new in this law; the only novelty is that we are learning of more agents which, when given in a certain way, illustrate it. These new facts, in regard to minute dosage, are suggestive and often useful, but they indicate no mysterious nor universal law.

* * *

The Small Fee System in Boston Dispensaries.—The plan of charging a small fee for medicines, which may be remitted at the discretion of the superintendent, has been adopted by the Boston dispensaries.

Reviews and Notices of Books.

THE PRACTITIONER'S REFERENCE BOOK. By RICHARD J. DUNGLISON, A.M., M.D. Second Edition, revised and enlarged. Philadelphia: Lindsay & Blakiston. 1880.

WE can heartily commend this book as one that must prove very useful to the general practitioner. This, the second edition, is larger, almost by half, than the first, and the book is much more satisfactory and complete. The additions that have been made include chapters on How to Write Metric Prescriptions; Directions as to the Use of the Hypodermic Syringe; How to Use a Galvanic Battery; How to Apply Trusses in Herniæ; How to Use the Clinical Thermometer; How to Prepare Stained Sections of Animal Tissues; Reference Tables of Size, Weight, and Specific Gravity of all the Organs of the Body; Celebrated Prescriptions or Remedies; Therapeutics of the Bowel Affections of Children; Diagnostic Tables of the Principal Fevers; also of Acute Pulmonary Diseases; of Diseases of the Larynx, and Naso-pharynx, and of Tumors of the Groin; Ready Reference Table of Antidotes, on a new plan. Rules of Medical Etiquette.

The above list will show how the book has been enlarged and will also give an idea of the general character of the work to those unacquainted with the first edition.

ON THE RELATIONS OF THE MEDICAL PROFESSION TO THE TRADE INTERESTS OF THE MATERIA MEDICA, and A NOTE ON PEPSIN. By EDWARD R. SQUIBB, M.D.

IN this valuable pamphlet, Dr. Squibb relates certain occurrences, in the Kings County Medical Society, which came very near to being discreditable. He also gives us some interesting facts in regard to the value of the different kinds of pepsin now in the market.

It seems that a gentleman read a paper before the above Society "On a Ready Method of Testing Pepsin," by which it was apparently shown that the pepsin of a certain manufacturer was much superior to all other kinds. The paper was referred to the Committee on Publication, and came very near being printed in the Society's journal, to the great advantage of the manufacturer of the particular pepsin in question.

Dr. Squibb shows the questionableness of the performance on any ground, and then proves that the test proposed was not a reliable one, and that the pepsin so much lauded is not any better than other kinds. From experiments, which he made, he concludes that the pepsins of the market are not pepsin at all, but rather concentrated peptones. They do, however, excite digestive fermentation, and practically may be regarded as pepsin. Another practical deduction is that by giving the pepsin with hydrochloric acid and a little nitrogenous food, half an hour or more before meal-time, a quantity of active peptone may be produced sufficient for the larger mass of the approaching meal.

A SYSTEM OF MEDICINE, Edited by J. RUSSELL REYNOLDS, M.D., F.R.S., with numerous additions and illustrations, by HENRY HARTSHORNE, A.M., M.D., in three volumes. Vol. III. Philadelphia: Henry C. Lea's Son & Co. 1880.

WE have already presented the chief features of this work in a review of the first and second volumes. The present and last volume is known to the profession through the English edition, and does not now need extended notice. It embraces diseases of the digestive, blood glandular, urinary, and cutaneous system. In diseases of the digestive system, the work has been done by Wilson Fox, Squarey, Wardell, Bristowe, Begbie, Goodeve, Curling, Anstie, and Maclean. Dr. Hartshorne has added chapters on cholera morbus and cholera infantum. Diseases of the blood-glandular system are treated of by Wardell, Gowers, Wilk, Beigel, and T. Lauder Brunton. Dr. Hartshorne adds bronchocele and progressive pernicious anæmia. Most of the chapters on the diseases of the urinary organs are by Dr. Roberts, but Drs. Basham and Beck, and Sir Henry Thomson, contribute each a chapter. Dr. Grailly Hewett writes two chapters of those devoted to diseases of the female reproductive organs. Drs. Priestley and John Williams finish the section. Dr. Hartshorne, at the close, gives a chapter on spermatorrhœa. Dr. J. Balmanno Squire writes of diseases of the cutaneous system.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 12, 1880.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

RUPTURE OF ANEURISM OF AORTIC VALVE, WITH AMYLOID DEGENERATION OF LIVER, KIDNEYS, AND INTESTINAL MUCOUS MEMBRANE.

DR. G. L. PEABODY presented specimens of the above, with the following history:—The patient was a laborer, fifty-four years of age, whose history is unsatisfactory. He was under observation only three hours. He was admitted to the New York Hospital on May 8th, at 6 P.M. Immediately after admission he had a convulsion. His urine was loaded with albumen. He was treated by the hot-air bath, and was given pilocarpine subcutaneously. He had repeated convulsions, and died at 9 P.M. on the same day. His wife said that he had been complaining for four months.

The autopsy was made fourteen and a half hours after death. He had cicatrices over both shins, and there was slight œdema of both legs. The chief point of interest was the heart, which I show you here. The left ventricle was slightly dilated, and one of the segments of the aortic valve was found almost entirely covered, on its ventricular aspect, with a thick layer of fibrine. It forms a much larger pouch than does either of the other segments. About midway between its free border and its attached border is seen a rupture, large enough to allow a No. 2 English urethral sound to pass through it. At this point the elastic tissue is entirely destroyed. The muscular tissue of the heart was pale and flabby, but, microscopically examined, was normal. I regard the case as one of acute endocarditis.

Both kidneys presented the complex lesions of amyloid degeneration, as did also the liver. The mucous membrane of the ileum was similarly degenerated. The lymphatic glands were nowhere enlarged.

Dr. Peabody next presented a specimen of

CYSTITIS, WITH STRICTURE OF THE URETHRA, AND FISTULA OF URETHRA OF LONG STANDING, TOGETHER WITH NEPHRITIS AND SOFTENING OF THE BRAIN.

The patient was a mechanic, a native of Germany, unmarried, fifty-five years of age. He was admitted to the New York Hospital on May 4th. Said he had had headache, not localized, for fourteen days. The day before admission he fell in the street. On admission his temperature was 101°. His tongue deviated to the right side. Right pupil was contracted. left dilated. No difference in strength of hands, but both feeble. No paralysis. Some difficulty in swallowing. Speech was thick. Understanding good. Denied venereal disease. He soon grew stupid. His urine contained a large percentage of albumen, together with hyaline, granular, and epithelial casts. Difficulty in swallowing increased. His urine had to be drawn by catheter. He died with œdema of the lungs, on May 9th, five days after admission.

Autopsy, twenty-one hours after death.—The interest centred in the brain, and in the genito-urinary tract. The brain I cannot present to you, so that I will describe its condition very briefly. There was marked atheroma of the vessels at the base, even of small arterial branches. There was no thrombosis or embolism in any of the branches so far as they could be traced, but there was distinct softening, without discoloration, of the left corpus striatum. The ventricles were not larger than usual. The kidneys were pale, cortex thin, markings of cortex obscure, capsules adherent, and surface granular. Microscopically, the lesions of diffuse nephritis were found, the interstitial element predominating. The ureters were not dilated. The penis, which, together with the bladder, I show you here, displays a close stricture at the bulbo-membranous junction, which admits, with difficulty, a No. 2 English urethral sound. In the floor of the urethra, to the right of the frænum in the corona glandis, is a circular, fistulous opening, whose diameter is about one-quarter of an inch. It is lined by mucous membrane, and presents no signs of inflammation.

The bladder was tightly contracted, and shows very marked hypertrophy of its muscular wall.

Dr. Post exhibited a calculus removed by bilateral lithotomy, from a boy, aged nineteen years. The patient recovered without an unfavorable symptom.

RHINO-CHEILOPLASTY.

Dr. A. C. Post next exhibited a water-colored painting representing an almost entire deficiency of the upper lip, with a loss of the columna nasi and of a portion of the right ala nasi, with the following history :

Charles Gardiner, æt. 65. Twenty-two years ago he had a wart on his upper lip which remained stationary for many years, and gave him no trouble. Four years ago he applied an acid to it, after which it became sore and increased in size. On the 31st March, a female cancer doctor, whom he had consulted, applied a paste or ointment which was reapplied four times at intervals of one day each. After the fourth application a poultice was applied and renewed for several days, when, on the 14th April, a slough came away, involving all the disease, and with it nearly the whole of the upper lip, and portions of the nose. He applied at my clinic, on the 24th April, when cicatrization had taken place, leaving a deficiency of the upper lip, excepting a narrow strip about a centimetre in width toward the left angle of the mouth. There was no trace of the columna nasi, and there was a deep notch about fifteen millimetres in breadth at the lower part of the right ala nasi.

I sent the patient to the Presbyterian Hospital, where I performed the following operation, on the 1st of May :

I first made a flap of the narrow strip of the lip, which remained near the left angle of the mouth, excising its vermilion border and its cicatrized margin, and leaving it attached at its upper extremity, and raised it so that its cutaneous surface looked upward toward the nose, and its mucous surface downward. This flap was made to replace the lost columna nasi, its cutaneous surface being denuded, and applied to the denuded inferior margin of the nasal septum, and its extremity to a denuded margin of integument at the tip of the nose, and the flap was secured by fine sutures to the parts to which it was applied. In its new situation, the transplanted flap formed a good substitute for the columna, which had been destroyed, except that its position was oblique, its posterior attachment being considerably to the left of the median line. The rectification of this obliquity was necessarily left for a subsequent operation.

I then made a flap of skin and subjacent tissues on the right side of the mouth, extending through the whole thickness of the cheek, wide enough not only to form the right half of the upper lip which was to be constructed, but also to fill up the notch in the right ala nasi. The two horizontal lines which bounded this flap above and below, were carried back over the anterior edge of the ramus of the jaw, and were then curved downward and forward over the base of the jaw, approaching each other so as to leave a space of about twenty-five millimetres between them at the narrowest part. A transverse incision was made at the anterior part of the broad portion of the flap, separating the part designed to fill up the notch of the ala nasi, from that which was to be used in the construction of the lip. The part designed to repair the notch of the ala nasi was then trimmed to the proper shape, and the margin of the notch denuded to receive it, when the parts were secured to each other by sutures. A flap of the breadth required to construct the left half of the upper lip was then made by incisions through the left cheek, following in the main the same directions as those which had been made through the right cheek. The right and left flaps were then drawn together so as to meet in the median line, and constricting bands within the mouth were divided for the relief of tension. More resistance was encountered on the right than on the left side, and it was deemed necessary, in order to overcome this resistance, to divide the mucous membrane by a vertical incision about five centimetres behind the anterior margin of the flap. The flaps were then joined in the middle by two pin sutures, and a number of fine silken sutures. The margins of the wounds in the cheeks were also united by fine sutures, excepting that a small space was left to granulate between the flap used for the ala nasi and that for the lip, and a larger space, about thirty-five millimetres in length and twenty-five in breadth, behind the peduncle of the flap, taken from the right cheek. These spaces were covered with ravellings of lint smeared with collodion. The mucous membrane of the newly constructed lip was then drawn forward and attached to the skin by numerous fine sutures, forming a vermilion border. When the operation was completed, the patient was greatly improved in appearance.

Since the operation, the wounds have healed throughout a great part of their extent. The newly-formed columna has united with the nose. The notch of the right ala nasi is filled up with the flap which was adapted to it, and which is secure in its new position. The left half of the newly constructed upper lip is perfect, and its vermilion border is adherent throughout. The vermilion border of the right half has sloughed throughout its whole extent, and a small portion of the tegumentary flap has also sloughed. The open wounds, which were dressed with lint and collodion, are in a state of healthy granulation. The general appearance of the face is good. The cicatrices are not conspicuous, and the ultimate success of the operation is secured beyond reasonable doubt. A supplementary operation will be required to supply the deficiency of the right side of the lip, and to readjust the columna nasi.

OSTEO-SARCOMA OF SUPERIOR MAXILLARY BONES.

Dr. Post also exhibited a specimen of osteo-sarcoma, involving the superior maxillary bones and the left cheek, with the following history:

Fungous-growth from the alveolar and palatine portions of both superior maxillary bones, involving also the mucous membrane and sub-mucous tissues of the left cheek.

Henrietta Johnson; æt. 52; married; admitted into the Presbyterian Hospital, April 16, 1880. She was not aware that there had been any case of cancer in her family. She had generally enjoyed good health, but had lost many of her teeth, and had worn a plate with false teeth for fifteen years, and she thought that the plate had irritated her mouth. Fifteen months before her admission she had noticed several small white spots on the inside of her right cheek. As they appeared disposed to spread, she had them cauterized, and they healed. They afterward reappeared, and increased in size. During the last winter they had occasioned so much irritation that she was obliged to remove her false teeth. They were painless at first, but during the winter they had become painful. Three months before her admission, they began to discharge a small quantity of odorless fluid.

At the time of her admission, an extensive fungous-growth occupied the alveolar and palatine portions of both superior maxillary bones, and a large portion of the mucous membrane and submucous cellular tissue of the left cheek. There was also a similar growth, but less extensive and more superficial, occupying a portion of the mucous membrane of the right cheek. The superficial fungous-growth from the right cheek was treated by the application of strong sulphuric acid, three times a week, and within a fortnight it nearly disappeared. On the 4th of May I removed the tumor, which occupied the two superior maxillary bones and the left cheek. The patient was prepared for the operation by the administration of half an ounce of brandy, with a little water, followed by a hypodermic injection of eight minims of Magendie's solution of sulph. morphiæ, and the administration of ether as an anæsthetic. I began the operation by performing tracheotomy, which was attended with some difficulty, in consequence of two large veins over the trachea, requiring to be tied in two places and divided, and also in consequence of the trachea being displaced backward and to the left by an abnormal-growth of the consistence of fibro-cartilage, which seemed to be attached to the isthmus of the thyroid-body. When the trachea had been freely opened by an incision through its anterior wall, I did not introduce a tube, but I adopted the method of Dr. Martin, of Boston, attaching, by suture, each lip of the tracheal wound to the corresponding lip of the cutaneous incision, and to the doubled end of a strip of adhesive plaster, and then drawing the two strips of adhesive plaster in opposite directions around the neck, thus keeping the edges of the tracheal incision widely separated from each other.

Having completed the tracheotomy, the ether was administered through the tracheal incision, and the mouth and nose were left free for the further steps of the operation. To prevent blood from flowing into the air-passages, a large sponge with a strong thread tied around it was crowded into the fauces. An incision was then made through the median line of the upper lip, and extended on each side through the upper lip at its junction with the nose, through the cheek at its junction with the nasal pyramid nearly to the inner canthus, and then parallel with the infra-orbital brim to a point near the outer canthus. On the left side, as more room was required for the removal of the portion of the tumor which involved the cheek, two additional incisions were made, each about five centimetres in length, extending downward and outward from the external commissure of the lips, and from a point near the external commissure of the eyelids. The extensive flaps bounded by these incisions were then dissected up from the subjacent parts, and the interior of the buccal cavity was thus fully exposed to view. The tumor was then separated from its attachments by means of bone-forceps and scissors, the portion of the morbid growth occupying the mucous and submucous layers of the left cheek being dissected off from the subcutaneous layers, there being a distinct boundary of healthy adipose tissue between the tumor and the skin. In prosecuting the dissection between the tumor and the ramus of the lower jaw, a large artery was divided, supposed to be a branch of the internal maxillary. The hemorrhage from this artery was controlled by pressure with a sponge, while I prepared to secure the vessel with a ligature. I succeeded in passing a curved needle armed with a double ligature through a mass of tissue enclosing the artery, and by tying the threads on each side I succeeded in arresting the hemorrhage. A small portion of the morbid growth was left behind in this region, and I thought it most prudent to postpone its removal by the actual cautery to a subsequent operation, as the present operation had been quite protracted, and the patient was somewhat exhausted. In the course of the operation, I had occasion to secure a number of bleeding vessels by ligature, and by the application of the Pacquelin cautery. Toward the close of the operation, when the pulse began to flag, I directed a hypodermic injection of thirty minims of brandy, which was repeated after a short interval. I also directed an enema of an ounce of brandy with three ounces of warm milk. I washed the extensive wound with carbolic acid, one to forty, and united its edges with fine sutures. After completing the closure of the wound upon the face, I placed a roll of lint within the mouth, to support the upper lip and the cheeks. I also withdrew the sutures from the tracheal incision, and allowed the edges of the wound to lie in contact.

There are several points in connection with this case which I deem worthy of special notice. The preparation of the patient for an operation, which was foreseen to be long and bloody, by the administration of brandy, and by the hypodermic injection of morphia before the inhalation of ether, appears to me very important to the safety of the patient, and to the comfort of the operator. The brandy helps to maintain the force of the circulation, and diminishes the tendency to extreme prostration in protracted operations. The morphia keeps the patient in a more quiet state of anæsthesia than can be easily and safely maintained by ether alone. In the present case there were very considerable intervals in which the patient slept quietly during the operation while the inhalation of the ether was discontinued.

The performance of tracheotomy as the initial step of an operation in which extensive incisions are made in the deeper parts of the nasal and buccal cavities, seems to me to add greatly to the safety of the patient by preventing the flow of blood into the air-passages, and it greatly facilitates the operation by allowing the uninterrupted inhalation of the anæsthetic as long as it is required.

The maintenance of the opening in the trachea, without the introduction of a tube, appears to me to be a vast improvement upon the old method which requires the introduction of a tracheal tube. For this improved method of maintaining the opening in the trachea, the profession is under great obligations to Dr. Henry Austin Martin, of Boston. The advantages of this method are that it maintains a larger opening for the entrance of air, and for the escape of blood and mucus than can be maintained by a tube; that it occasions much less irritation; and that the trachea is very much less liable to be clogged than when a tube is inserted. The flow of blood into the trachea is more readily and more effectually prevented by crowding a sponge into the fauces than by the use of a Trendelenberg's tube. In the course of my operation a little blood escaped into the trachea, but I found it a very easy matter to swab it out with a small piece of sponge held in the grasp of a forceps.

The condition of the patient since the operation, has been in all respects satisfactory.

SARCOMA OF ORBIT.

Dr. C. S. Bull presented a specimen of the above with the following history:

James Hoey, æt. 22. Dec. 15, 1879. Ptosis and exophthalmus of left eye for two weeks, steadily increasing. Convergent squint in left eye since childhood. Motion of eye limited in all directions, but mostly outward and inward. No bruit, or pulsation, or thrill of any kind. $V=\frac{20}{20}$. No limitation of field, and no abnormality in the retinal circulation. No pain.

Dec. 22d.—Constant dull pain for two days in orbit. Chemosis of ocular conj. over ext. rect. muscle. Narrowing of arterial calibre on disk; some signs of perivasculitis. Heart examined, and faint regurgitant murmur at apex heard, also murmur at the base with each sound.

Dec. 24th.—On floor of orbit, reaching from infra-orbital notch to canthus externus, can be felt a hard, resisting growth, which presses the lower lid forward, and this can be followed for some distance back into the orbit. Very sensitive on pressure, and the seat of a constant dull pain. $V=\frac{40}{200}$, and with $+14=\frac{20}{50}$. Operation for removal of the tumor advised and declined, and patient disappeared from view till Feb. 26, 1880. Exophthalmus then very marked. Eye shoved upward and inward. Lower half of cornea opaque and necrotic; upper half anæsthetic. Dense infiltration of palpebral and ocular conj. below horiz. meridian. Lower lid completely everted, and eyeball immovable. V=faint perception of light. Orbital growth very prominent at external angle. Pain very severe and constant. Well-marked signs of orbital cellulitis. Patient very anæmic and exhausted. Enucleation of tumor the same day with comparative ease. It was loosely adherent to orbital tissue, and somewhat firmly, at one point, to sheath of optic nerve. After its removal orbital tissue found so densely infiltrated, and signs of cellulitis so well marked, that it was deemed best to enucleate the eyeball.

March 20th.—Orbital tissue and conjunctiva so infiltrated as to project between the lids, and a plastic operation was necessary to restore the tissue to its place, and make room for an artificial eye.

April 5th.—Well-marked signs of recurrence of tumor in tissue on floor of orbit, the lower lid being pushed forward.

April 13th.—Second operation for removal of growth. External canthus incised, and inferior tarsal ligament divided. Growth found to be closely adherent to periosteum of lower margin and floor of orbit, and reached back to apex. Very vascular and not encapsulated. Patient lost a great deal of blood. Orbit was completely cleansed, and periosteum stripped up from margin and floor of orbit for some distance backward. Orbit then washed out by solution of carbolic acid (1 to 20), but hemorrhage was continuous, and orbit had to be plugged. Violent reaction followed in skin and subcutaneous tissue of lids, cheek, and temple. On third plug had to be removed, and on washing out the cavity the hemorrhage returned. This was checked with hot-water thrown in with a syringe. The patient passed safely through an attack of cellulitis of the corresponding side of face, and at date of present writing (May 23d) there are no signs of a recurrence of the tumor, and the orbit is granulating well from the bottom.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Fourteenth Annual Meeting,

Held in Princeton, May 25 and 26, 1880.

(Special Report for The Medical Record.)

Tuesday, May 25th—First Day.

The Society met in the lecture-room of physics, in the School of Science building, at 8 o'clock P.M., and was called to order by the President, Dr. A. W. Rogers, of Paterson. Vice-presidents Drs. A. N. Dougherty, L. W. Oakley, and John W. Snowden, and others, were in their respective seats. Prayer was offered by the Rev. Dr. Murray, of Princeton.

The President of Princeton College, Dr. McCosh, and other members of the faculty, the resident clergy, and all physicians who were present, were invited to seats during the sessions of the Society, as corresponding delegates.

The Committee on Organization reported the list of delegates. Notwithstanding the intense heat of the day, there was a large attendance of members.

ANNUAL ADDRESS OF THE PRESIDENT.

The President read the annual address, the subject of which was the personal ethics of the physician, embracing his aspirations, motives, habits, and affinities, which clothe him as an atmosphere, and make him what he is and hopes to be.

The various committees were announced by the President.

S. Wickes, M.D., offered his resignation as Chairman of the Standing Committee, stating that he had held the office for twenty years, and that he had taken much pleasure in the discharge of its duties, but felt that the time had come when he should withdraw from the position. After the expression of warm appreciation of his services by members of the Society, his resignation was accepted, and, on motion of Dr. D. S. Smith, the following resolution was adopted:

Whereas, Dr. S. Wickes having resigned his position as Chairman of the Standing Committee, a position which he has held for twenty successive years, discharging its duties with delicate tact, accurate knowledge, and untiring energy; therefore, be it

Resolved, That the thanks of this Society are markedly due to him, and are hereby tendered to him, for the manner in which he held himself in that important position.

Dr. McCosh, the President of the College, extended an invitation to the members of the Society to call at his house socially, after the adjournment, which was accepted. Adjourned.

Wednesday, May 26th.—Second Day.

The President in the chair.

Delegates from corresponding societies: Dr. Charles O'Lary, from Rhode Island Medical Society, Dr. Robert Newman, from the Medical Society of New York, and Dr. John C. Pennington, from the Medical Society of Massachusetts, on their presentation, duly responded, and in return were cordially welcomed by the President.

The Corresponding Secretary read letters of regret at inability to attend from Drs. Ferris Jacobs, of New York, Prof. J. C. Hutchison, of Brooklyn, and Dr. Oscar Allis, from Philadelphia.

Drs. S. Wickes and Joseph Parrish, honorary members, were present.

THE MEDICAL HISTORY OF THE PAST YEAR IN NEW JERSEY.

The report was read by Dr. Wickes, the chairman of the committee.

In the review of the reports, the medical history of the year may be summed up as follows:

First. An unusual freedom from diseases of the intestinal canal.

Second. Less scarlatina, diphtheria, and other contagious and infectious diseases, than for a long series of years before.

Third. A moderate amount of the diseases of the air-passages, without marked fatality.

Fourth. Small-pox is reported in one town only, viz., Salem, where ten cases occurred, supposed to have been imported from Philadelphia. Two proved fatal.

And lastly, an almost universal prevalence of fevers of malarial origin, generally mild in type, amenable to treatment and seldom fatal. This statement is very suggestive, contrasted with the report of the standing committee twenty years ago, when, after carefully collating information obtained from all parts of the State, the committee reported thus: "There is a general subsidence of miasmatic diseases everywhere, and in almost all the counties of the State noticed . . . . intermittents may be said to have ceased to exist."

Dr. Condit, of Morris, reports great success in the treatment of influenza with jaborandi to the production of free diaphoresis.

In Essex County, cresylic acid has been found valuable in the treatment of pertussis, by Dr. Love, while Dr. Wilmurth uses with success in the same diseases, oxalate of cerium, administering a single daily dose of two to four grains.

Dr. Hunt enters a protest against so-called "new remedies" in the following vigorous language:

"New remedies follow each other with the painful haste of the plagues in Egypt. As a rule the newest is less useful than the predecessor it displaces. The druggists usurp the methods of the quacks, and with a cool audacity prey upon the profession. Instead of issuing almanacs they print journals, with a meagre ballast of stale medical information copied from reputable sources, and pages of self-laudatory advertisements and certificates from bogus or pliant doctors, of this or that impossible preparation . . . . A publication of this class just received contains an infamous advertisement of medical scholarship certificates, transferable, for sale by parties in Philadelphia. So these men assist in aspersing the character of medical diplomas in that city."

The questions offered by the committee for the consideration of our medical men were:

1st. The therapeutics of aconite.

2d. The relief of the headaches of the menstrual period.

Replies to the first question show that, though not in general use, aconite is employed by a very considerable proportion of physicians the record of whose experience furnishes quite a satisfactory estimate of its claim to general adoption.

A summary of its properties shows that it is useful in pneumonia and other inflammations of the respiratory organs, particularly when of sthenic type; in fevers of high grade and with inflammatory action; in eruptive fevers with high temperature; in all mucous inflammations of a tonic character, and in facial erysipelas. It is an arterial sedative, and allays nervous irritability, is useful in neuralgia locally, increases the action of the skin and kidneys; but its special value is to reduce the force and frequency of the heart's action, and lower the temperature.

The answers to the second question have been full, and have ably met the purposes of the inquiry. But the complex nature of the various pathological conditions involved prevent the committee formulating these opinions without extending its report to too great length.

The committee called the attention of the Society to the report of the semi-centennial anniversary of the Burlington District Society; to the circular of the Department of the Interior regarding bogus medical diplomas; and to the act, passed at the last session of the State legislature, regulating the practice of medicine and surgery, which forbids any person to practice medicine in the State unless he or she be a graduate of some regularly chartered institution, who shall file a copy of his or her diploma with the clerk of the county of residence, paying to him ten cents therefor, with penalties for nonconformity to the requirement. It further makes the offer of a diploma issued to another, or a diploma issued or obtained fraudulently, a high misdemeanor, with heavy penalties upon conviction.

The necrology of the year is as follows:

Dr. Samuel Lilly, of Lambertville; Dr. Zachariah Read, of Burlington; Dr. I. S. English, of Monmouth; Dr. Marshall Paul, of Burlington; Dr. Stephen Personette, of Essex; Dr. W. M. Woodruff, of Elizabeth; Henry Ward, of Newark.

Delegates to corresponding societies read their reports: Dr. S. H. Pennington, to Rhode Island; Dr. Townsend, to Pennsylvania.

Drs. J. C. Hutchinson, of Brooklyn, and Prof. Brackett, of Princeton, were elected honorary members of this Society.

The Corresponding Secretary read his annual report.

The Committee on Treasurer's Accounts reported that it had examined the accounts of the Treasurer and found them correct. Also recommended that the assessment for next year be two dollars per capita for members of district medical societies.

The following persons were proposed for honorary membership: Prof. T. A. Emmett, of New York, by Dr. L. W. Oakley; Dr. Isaac Taylor, of New York, by Dr. H. G. Taylor; Dr. Janeway, by Dr. Beard; Prof. T. G. Thomas, by Dr. A. N. Dougherty.

THE ABUSE OF THE OBSTETRIC FORCEPS.

Dr. Snowden, of Camden, read a paper entitled, "The Abuse of the Obstetric Forceps." After portraying the dangers to the perineum and cervix uteri from the too early and rash use of forceps, and quoting many eminent authorities in support of his views, the doctor concluded as follows: "It is not the aim of this essay to oppose the proper use of the forceps, but it is the unnecessary use in the hands of the skilful operator, and the misuse and its fearful consequences under the management of the unskilful, which should be deprecated by the thoughtful members of the profession."

SOME OF THE PHENOMENA ASSOCIATED WITH ANÆSTHESIA.

Dr. P. V. Hewlett, of Newark, read a paper "Upon the Peculiar Hallucinations incident to the Production of Artificial Anæsthesia, and the Persistence of their Effects upon the Minds of those subjected to its Influence, and upon the Question how far this Condition should affect the Credibility of any Person as to the Events transpiring during the Inhalation, with its Medico-legal Bearings." The doctor considers the physiological effects of anæsthetic agents, and divides the stages into three, which he describes as follows:

The first stage, that of inebriation, which is usually agreeable; consciousness is impaired, vision is slightly affected, though sensation is but slightly blunted. In this stage a person's testimony is reliable, but there is sufficient power of resistance to violence.

The second stage. Here the mental functions are impaired, but not entirely suspended; consciousness is imperfect; a sort of dreamy state supervenes; the subject is intoxicated, not dead-drunk, but in the condition described by the law as drunk and incapable.

The third stage, where all voluntary motion is paralyzed, the mental faculties in complete abeyance, etc.

In the second and third stages, the mental functions are so impaired as to render them incompetent to act as reliable witnesses.

The doctor quotes many instances of prosecutions for rape made by women who have been anæsthetized, against the administrators of the anæsthetics, and after analyzing them draws the following conclusions:

First. That if a person be fully anæsthetized, she cannot be a competent witness, as no one can give credible testimony who is unconscious and insensible at the time she professes to describe her sensations and feelings, whether these sensations are painful or pleasurable.

Second. That if the person is not fully anæsthetized, she is not a credible witness, for if she is in the second stage or degree of anæsthesia, she may be laboring under the delusions and hallucinations common to this stage; and,

Third. If she is in the first stage, and claims she was conscious but unable to offer resistance, the assertion is so inconsistent with the thoroughly well-known facts and phenomena uniformly attending the administration and use of these agents, it should be looked upon as false—for all authorities agree that during the first stage the intelligence is not affected, and consequently the power of resistance is not lost.

MECHANICAL TREATMENT OF ABNORMAL CONDITIONS OF THE ANKLE-JOINT.

Dr. C. F. Stillman, of Plainfield, gave a very interesting and instructive address on the mechanical treatment of abnormal conditions of the ankle-joint, which he fully illustrated by diagrams and apparatus.

OFFICERS FOR 1881.

The following were elected as the officers for the ensuing year:

For President.—Dr. A. N. Dougherty, of Newark.

For Vice-Presidents.—Drs. L. W. Oakley, John W. Snowden, and S. Wickes.

For Corresponding Secretary.—Dr. Wm. Elmer, Jr., of Trenton.

For Recording Secretary.—Dr. Wm. Pierson, Jr., of Orange.

For Treasurer.—Dr. W. W. L. Phillips, of Trenton.

For Standing Committee.—Drs. Joseph Parrish, C. J. Kipp, and S. S. Clark.

For Delegates to American Medical Association.—Drs. J. S. Cramer, F. W. Miller, David Warman, J. H. Love, J. D. Heratage, J. S. Long, J. A. Currie, D. S. Hardenburg, Thomas Ryerson, J. S. Whitaker, and N. Williamson.

For Delegates to Massachusetts Medical Society.—Drs. C. F. Stillman, Thomas Ryerson, and D. C. English.

For Delegates to Connecticut Medical Society.—Drs. H. G. Wagoner, H. C. Buckingham, and H. A. Hopper.

For Delegates to Rhode Island Medical Society.—Drs. D. Benjamin, F. W. Miller, and W. M. Baird.

For Delegates to Pennsylvania Medical Society.—Drs. E. P. Townsend, I. H. Griffith, and G. H. Dickinson.

For Delegates to New York Medical Society.—Drs. I. S. Green, D. A. Currie, and A. C. Hoffman.

It was voted that the next place of meeting should be at Long Branch.

The following resolutions were adopted:

"*Whereas*, The Salem County District Medical Society has for many years failed to maintain a complete organization, and has not been represented in the State Society by its delegates, and in consequence thereof the Society has been dropped from the roll of societies represented in the State Society; and whereas the said Society has reorganized, adopting a constitution in accordance with the constitution of this Society; therefore,

"*Resolved*, That the Salem County District Society be restored to the roll of societies in connection with the Medical Society of New Jersey.

"*Resolved*, That the accredited delegates of the Salem District Society be admitted to seats as members of this Society upon conforming to the usual rules regulating the admission of delegates, and upon condition that Article 2 and Article 12 of its constitution be altered according to the suggestion of the Standing Committee."

BOGUS DIPLOMAS.

The following was adopted:

"*Whereas*, It has come to the notice of this Society that spurious diplomas emanating from Philadelphia, Penn., from colleges which have no legal existence, have been offered for sale in foreign countries, to the great disgrace of the United States of America; and whereas the State of New Jersey, at the last annual session of its legislature, has deemed that no one shall practise medicine or surgery within its bounds except under a diploma from a legally authorized college or medical society; therefore,

"*Be it resolved*, That the members of the several district medical societies solicit the county clerks in their respective counties to carefully inspect all diplomas submitted to them for registration, to see whether they are in accordance with the law, and that district medical societies be requested to secure the record of all physicians in their respective counties, as required by law, and report to this Society, to the end of purifying the profession and protecting the public from imposture.

"*Resolved*, That a copy of these resolutions be transmitted to the Hon. John Eaton, of the Bureau of Education at Washington, and that he be requested to send to the Recording Secretary of this Society a list of such colleges as are recognized at the Bureau of Education at the seat of government."

PRELIMINARY EDUCATION.

DR. E. V. TOWNSEND offered the following, which was adopted:

Resolved, That it shall be the duty of each county society of this State to appoint a committee of three of its members, who shall examine all applicants for the study of medicine, as to their mental and moral fitness for the profession, and no member of such county society shall admit a student into his office, unless he possesses an acceptable certificate from said committee, or a diploma or certificate of graduation from some respectable institution of learning.

On motion of DR. GAUNT, it was

Resolved, That the reporters of the district medical societies, respectively, shall issue the following to the members of their respective societies:

1st.—What do you consider the cause of intermittent fever? 2d.—What do you consider the cause of malarial fever? 3d.—What do you consider the cause of typho-malarial fever? 4th.—What do you consider the cause of typhoid fever?

THE NEW JERSEY SURGEONS IN THE REBELLION.

On motion of DR. OAKLEY, the following resolutions were adopted:

Whereas, In the History of the Medical Men and Medicine in New Jersey, by Dr. S. Wickes, in his sketch of Dr. James de Benneville is found this passage: "He was a surgeon in the war of the rebellion, and one of those brave men who refused to desert his hospital when captured before Richmond, though many did";

And whereas, The statement not being in keeping with the facts, and being unsupported by any reliable evidence, is calculated to do injustice to the medical officers of the army, to those from this State who did their duty conscientiously and fearlessly, and if uncontradicted, would leave a stain in history upon the memory of those now living, as well as upon that of their dead professional comrades—therefore,

Resolved, No facts have come to the knowledge of this State Medical Society, in regard to any surgeon from New Jersey, which can in any way authorize the above statement.

Resolved, That a copy of this preamble and these resolutions be placed upon the minutes of this Society, to counteract, as far as possible, any erroneous impressions which may be left by the passage referred to.

On motion, it was agreed to continue the publication of the old records of the Society. Dr. Wickes was appointed on the Committee of Publication.

Adjourned.

◆

MASSACHUSETTS MEDICAL SOCIETY.

Ninety-ninth Annual Meeting.

THE ninety-ninth annual meeting of this society was held in Horticultural Hall, Boston, on Tuesday and Wednesday, June 8 and 9, 1880.

As usual, the first day was wholly occupied in the reading and discussion of medical papers.

PNEUMONITIS.

The first paper, on pneumonitis, by Dr. C. D. Hunking, of Haverhill, was largely devoted to the consideration of whether the disease in question was of a constitutional or local character. The writer's conclusions were:

First.—In regard to its character. Croupous pneumonitis, according to high authority, is considered to be an acute, non-contagious, but infectious disease.

Second.—As to treatment. This consists mainly in supporting the action of the heart, and controlling the fever by anti-pyretic remedies and stimulants. Attention should be given to the nutrition of the patient, and pain and insomnia relieved by appropriate remedies. In convalescence chalybeates are indicated.

In an animated discussion which followed the reading of the paper, one member remarked that much of the treatment of pneumonia of late had been with the view of its being an infectious disease. The disease will sometimes follow erysipelas of the face, seeming to be a continuation of the disease by the mucous surfaces from the nose and pharynx downward, rather than from a septic poisoning of the system. The evidence of croupous pneumonia being followed by phthisis is said to be small, yet the speaker knew of a case where the pneumonic dulness did not clear up, and post-mortem examination showed solidification of the lung, and even cavities formed.

Another speaker referred to the importance of sustaining patients from the beginning of the disease; give nourishment and tonics; avoid anodynes as much as possible. The fl. ext. of jaborandi, ten drops, with two grains of quinine, given every two hours, has been a favorite form of treatment.

Another member said he recollected when it would have been considered criminal not to bleed patients suffering from pneumonia, although the fashion has passed away. He thought fully as large a percentage of patients recovered then as under the modern treatment.

A paper on

PYÆMIA OF DOUBTFUL ORIGIN, APPARENTLY SPONTANEOUS.

was read by Dr. C. H. Cook, of Natick. It was based upon a case of a lady under the care of the reader, in whom symptoms of pyæmia developed without any discoverable traumatism. The post-mortem examination showed abscesses of the thigh, burrowing in between its muscles. In the posterior and middle portion of the lower lobe of the right lung there was found an abscess containing ℥j. of pus, and the pulmonary artery contained an embolus corresponding to the location of the abscess. The left kidney contained a wedge-shaped abscess at its upper extremity. There was also a larger abscess in the right kidney, near one of the pyramids. The liver, on microscopic examination, showed extreme fatty infiltration, and some fatty degeneration of the hepatic cells. The right buttock was found to be a bag of pus. No source of pus was found.

The subject of the third paper, by Dr. A. T. Cabott of Boston, was

ANTISEPTIC TREATMENT OF EMPYEMA.

The reader held that the use of the spray in operating for empyema is of value—though denied by some—and gave the details of his method of operating, and the history and results of cases observed by him.

Dr. H. F. Borden, of Brockton, read a paper on

ŒDEMA OF THE LUNGS, WITH ILLUSTRATIVE CASES.

The cases reported were those of sudden death, seemingly from acute pulmonary œdema. The reader discussed the pathology of such cases, and summed up his views as follows: In acute non-inflammatory œdema of the lungs, the conditions for its production are twofold. I. A cause or causes which first lead to accumulation of blood whose local pressure becomes greater than normal, varying in intensity according to the agents in its production. II. A loss of natural vitality and power to resist serous transudation in the walls of the vessels, brought about by a change in their nutrition, due to some abnormal condition, recognizable or not.

THE RELATION OF BACTERIA TO DISEASE,

was the subject of a paper by Dr. W. F. Whitney, of Boston. The paper gave a brief sketch of the classification and mode of development of these organisms, together with a consideration of the points in favor of regarding them as the originators of the diseases with which they are found associated. The disease, the parasitic origin of which is best established, is known as gangrene of the spleen—charbon. When communicated to men it has received the name of malignant pustule. The mode of development of the bacillus anthracis in this disease, as observed by Kock, was described. Another disease with which bacteria are intimately connected is recurrent fever. The natural history of the parasite in this disease is not as well known as is that of charbon. Septicæmia in mice, progressive necrosis of tissue (gangrene) in mice, progressive abscess-formation in rabbits, pyæmia in rabbits, as the result of experimentation, were also described. The occurrence of micrococci in the membrane of diphtheria, in the blood of persons suffering from erysipelas, were alluded to.

Dr. A. F. Reed, of Holyoke, read a paper entitled,

DIPHTHERIA, AND THE RESULTING PARALYSIS.

Its object, as stated, was to call attention to the nature of the poison of diphtheria, and also to some of the points relating to the origin and peculiarities of the resulting paralysis.

Dr. C. P. Putnam, of Boston, illustrated the

AMBULATORY TREATMENT OF HIP-DISEASE,

by the exhibition of a large number of patients, most of whom were wearing a splint of his own invention. This exhibition concluded the exercises of Tuesday.

The Society reassembled at nine o'clock A.M. on Wednesday, to enter upon the anniversary exercises. After the reading of the records of the last annual meeting, and of the Treasurer's report, a paper on

THE IMPORTANCE OF EARLY RECOGNITION OF EAR DISEASE

was read by Dr. J. O. Green, of Boston. The varieties of trouble resulting from inflammation of the mucous membrane of the tympanum were referred to, and the pathological processes resulting from originally slight and neglected causes, were mentioned. Many of the primary inflammations of the tympanum come on so insidiously, and with so little inconvenience to the patient, that the mild symptoms are ignored or forgotten, and too often relief is only sought when the functions of the ear have become greatly impaired, and pathological changes which cannot be cured, and perhaps but slightly alleviated, have resulted.

Dr. Peter Pineo, of Hyannis, presented a paper entitled

CAPE COD AS A HEALTH RESORT,

and some remarks pertaining to sanitary science. On the southern shore of this peninsula, from Falmouth to Chatham, a distance of forty miles in a straight line, there is a climate whose temperature is lower in summer and higher in winter, and less variable than elsewhere in New England. The summers, as a rule, are exceptionally dry. The soil is a light, thin, sandy loam; vegetation being scanty, is not sufficient to excite fears of malarial poison from its decomposition. The zymotic diseases were stated to be of rare occurrence, and the cases of diphtheria and enteric fever which had been seen by the reader had invariably been traced to a filth origin. The paper also enforced the importance of cleanliness in person and surroundings as the price of health—the great duty of life.

A demonstration of litholapaxy by its orinator, Dr. H. J. Bigelow, of Boston, was witnessed with great interest by the Society. Dr. Bigelow stated that the dogma taught by Civiale and the lithotritists who succeeded him, that the danger of irritation and inflammation of the bladder in the operation of lithotrity was in proportion to the time that the instruments were left in the bladder, had been held and taught by Sir Henry Thompson and others. But the true cause of the vesical irritation is the angular fragments of stone which are left in the bladder after crushing. Hence the importance of removing them at a single sitting. The urethra, as demonstrated by Otis, will tolerate a much larger instrument than those made by the old English scale. The success of the new process is due to the substitution of a larger tube than was used by Clover in his evacuating instrument. Dr. Bigelow exhibited his ingenious and effective lithotrite and evacuating apparatus.

Delegates from New Hampshire, Rhode Island, Connecticut New York, and New Jersey, were introduced to the Society.

The annual discourse, by Thomas H. Gage, M.D., of Worcester, was upon the "Possibility and the Practicability of the Prevention of the Spread of

Typhoid Fever." This he would accomplish by the disinfection of the intestinal discharges of fever patients. Alluding to the well-known fact that the disease, once introduced into a household or community, often attacks many of its members, he held to the doctrine that the malady often need not extend beyond the individual first attacked, and bringing the disease, provided his alvine discharges were properly disinfected. Reference was made to epidemics of typhoid fever arising from the contamination of the water supply with typhoid excretions which had not been disinfected. The views of Dr. Budd on the subject of disinfection and preventive medicine were quoted at length, and with approval. Reference was also made to the prevalence of typhoid fever and its ravages in this State during the past forty years.

At the close of the discourse, a vote of thanks was presented to the orator for his able and interesting address.

After the introduction by the retiring president, Dr. Lyman, of the president elect, Dr. Williams, the Society proceeded to the Music Hall to enjoy the festivities of the annual dinner.

The following officers were chosen by the councillors for the ensuing year:

President—Dr. Henry W. Williams, of Boston.

Vice-President—Dr. Asa Millet, of East Bridgewater.

Orator—Dr. J. Collins Warren, of Boston.

Anniversary Chairman—Dr. James C. White, of Boston.

The next annual meeting will be held in Boston on the second Wednesday in June, 1881.

Correspondence.

BENZOATE OF SODIUM IN PNEUMONIA.

To the Editor of The Medical Record.

Sir:—I take the liberty of writing to you in regard to my experience with benzoate of sodium in scarlet fever, diphtheria, and a peculiar epidemic form of pneumonia which has prevailed in this vicinity (and, as I understand, in various parts of the State) for the past three months.

I think I never used a drug with more satisfactory results, and am desirous that it be thoroughly tested by others.

I am sorry to say that I have kept no record of my cases, as I had no thought of publishing or otherwise using them until quite recently; consequently, can only relate circumstances from memory. Just about a year ago (July 17, 1879), I read an article in the *Boston Medical and Surgical Journal* relative to the use of benzoate of sodium in diphtheria and other diseases dependent on blood-poisoning, which impressed me so favorably that I determined to use it at the first opportunity.

I first used it in a case of puerperal fever. Under its use the fever soon subsided and the patient convalesced. The next case in which I used it was a case of diphtheria and scarlet fever combined, occurring in a boy ten years old. When first called to this case, I recognized it as a severe case of diphtheria, with no indications of any complication. The temperature was 104° F., profuse perspiration, and much prostration, with fauces pretty well filled with diphtheritic deposit.

Treatment was at once commenced with benzoate of sodium, in such doses as to use ʒ ij. every twenty-four hours. My prescription was as follows:

℞. Sodii benzoat.................... ʒ ij.
Aqua mentha pip................ ℥ ss.
Syrup aurantii.................... ℥ ss.
Aqua dest......................... ℥ iij.
M. Sig.—Dose, tablespoonful every three hours.

At the same time that I commenced with the benzoate, I prescribed tonic doses of quinine every four hours, and made use of a gargle, composed of tannin, gr. iv.; morphia sulphate, gr. j.; vinegar, four tablespoonfuls, and water, eight tablespoonfuls, alternating it with a gargle of saturated solution of potassa chlorate. The temperature fell half a degree during the first twenty-four hours, at which time the eruption of scarlet fever began to make its appearance. Contrary to former observations, the fever kept coming down at the same time the eruption and tumefaction of the skin progressed, so that when the eruption was at its height the temperature stood at 102°. The deposit in the fauces came off about the time the eruption had fully faded, the patient convalescing and gaining full strength much sooner than I expected.

Since then I have treated three other cases of uncomplicated diphtheria, with just as good results. In the beginning they were all bad cases, a malignant type of the disease being then prevalent in the community.

About six weeks since we commenced having pneumonia in an epidemic form. In some instances two and three cases would come down in the same family at the same time. There was in many cases much nausea, and often vomiting in the beginning of the difficulty; and in nearly all cases they complained early of a "bad feeling" in the region of the stomach and upper bowels. Moderate fever seemed to precede the lung trouble which soon followed, and was ushered in with high fever, the temperature often reaching 106°, and in some instances 107°.

My first cases were treated with large doses of quinine, to control fever and relieve congestion; expectorants and anodynes to relieve the cough; tonics and supporting measures to sustain the patient. Notwithstanding, all so treated were saved; most of them were terrible cases. I soon came to the conclusion that the inflammation of the lung was not the primary disease, but that it was dependent on some poison in the system, which, in being eliminated through the lung, or acting upon it in some way through the blood, produced congestion and inflammation. As soon as this conclusion was reached I felt that benzoate of sodium promised more than anything else, and immediately commenced using it.

Since then I have been called in all stages of the disease, from the initiatory fever, which has marked the cases in this vicinity (though some have commenced with a chill, like ordinary pneumonia), to the stage of softening and expectoration, and in every instance its use has been followed by the same results. The temperature soon begins to fall. The tongue exchanges its brown coating for a white one, and a dangerous case has soon changed to a hopeful one.

I will give you the history of a case that I was called to see, Friday, May 7th, 4 P.M. Patient, a married man, about forty years of age, had been feeling badly for about a week previous; complained of loss of strength; "bad feeling" in the region of stomach and upper bowels, and much pain through lower part of right lung. Had a severe chill at 2 P.M. the day before. Temperature, 106° Fahr. Tongue brown, considerably furred, put out with difficulty, and very tremulous. Much tremor of the hands. Lower half of right lung engorged and useless. Body covered with perspiration, and every indication of great prostration. Prescribed soda benz. ʒ ijss., syrup aurantii ℥ ss., aqua mentha pip. ℥ ss., aqua dest. ℥ iij.; mix; dose, tablespoonful every three hours; quinine in tonic doses every four hours; milk and beef-tea every three hours; mustard poultice to chest, to be followed by flaxseed-meal poultice; cold water sponging every twenty minutes, until the fever began to come down. With the exception of the cold sponging (which was only kept up for a few hours), this treatment was continued until convalescence was established. Saturday, May 8th, 3 P.M.—Temperature, 104¾°; tongue, about half of it covered with white fur; patient's general appearance much better. Sunday, May 9th, 11 A.M.—Temperature, 96½°; tongue covered with white fur; patient comfortable, but very weak. Monday, May 10th, 11 A.M.—Temperature, 99°; ordered enema, to move bowels. Tuesday, May 11th, 11 A.M.—Lung very sore, which is felt when attempting to move, but free from pain when keeping still. Wednesday, May 12th, 11 A.M.—Temperature, 97°.

As a result of its use in pneumonia I have observed the temperature to lower, coming steadily down. The brown coating of the tongue disappears, and a white coating, very much like that produced by the use of turpentine in enteritis, makes its appearance; the cough softens and expectoration is free, and in a very few days the patient is left with simply a sore lung and weakness to recover from. The duration of the attack having been much shorter, of course recovery is more rapid. The dose, as given in the journal, is, for children between one and three years of age: ʒ ij. of the sodium dissolved in three and a half ounces of the vehicle, given so as to use all in twenty-four hours, in half to tablespoonful doses. Infants may use ʒ j. in the same way, only in smaller doses, given more frequently, but so to consume the whole in twenty-four hours. Children between three and seven should use from two to two and a half drachms. Those over seven take from ʒ ij. to ʒ iv., and adults from ʒ ijss. to ʒ vj. daily.

The author states that "an unpleasant after-effect has never been observed, not even in young infants." This accords with my experience. The diphtheritic membrane was treated with powdered benzoate of sodium, applied through a tube.

I desire to call the attention of physicians to this drug, and should be glad to have them test its merits and report. Yours truly,

C. B. CADY, M.D.

SHEBOYGAN FALLS, WISCONSIN, May 12, 1880.

* * *

MEDICAL SOCIETY OF THE COUNTY OF WESTCHESTER.—The Eighty-second annual meeting of the Medical Society of the County of Westchester was held at White Plains, Tuesday, June 15th. A large number of the profession of the county were present and the meeting was one of unusual interest and profit. Reports of delegates to the National and State Societies indicated that they had been faithfully at tended and with signal benefit.

POISONING BY CORNED BEEF.

To the Editor of The Medical Record.

SIR:—On the morning of June 15th I was asked by a messenger to visit Fort Lee and attend to some people who, as he stated, had been vomiting all night, and were thought to have been poisoned.

On arriving at Fort Lee, I found that during the past night, between twelve and one o'clock, about eight or a dozen people, mostly employees, had been seized with violent nausea, vomiting, and purging, preceded by a bitter metallic taste in the mouth. The character of the vomited matter in color was "green as grass" and in taste very bitter.

Of course, this history led me to suspect poisoning, and in further pursuing my investigation I learned that for dinner the night before these people had eaten largely of corned beef and lettuce. Having read not long ago a case of poisoning by lettuce, I was led to look at that, or the parasitic poison which might have been connected with it, as the possible cause; but my mind was soon disabused of this idea on learning that they had long eaten of this article of food, and that those who had eaten of the lettuce and not of the corned beef had escaped entirely, while all who had eaten at all heartily of the beef were invariably affected. The connection of these symptoms so closely with the last meal led me, without doubt, to connect them with it. On making inquiry of the cook concerning the corned beef, I was told that it could not possibly be due to the corned beef, as it was very nice and had been prepared by himself, remarking that had it been pressed beef it would have been different. I subsequently learned that the beef *had* been prepared by the cook, and that in copper vessels. This, of course, immediately cleared the case, and put it beyond all doubt in my own mind. Most of these persons were convalescent, with considerable nervous exhaustion and gastro-intestinal irritation.

Although this meat has not yet been chemically examined, no doubt could exist in the matter, and this article of food was requested to be discontinued from the bill of fare. The lesson to be derived from these cases is that copper vessels *should not* be used in preparing food, because no matter how clean they may be kept, there always exists a possibility of danger; and if people will not learn this lesson themselves, it would be well to make it a criminal matter.

JUDSON C. BROWN, M.D.

208 WEST 125TH STREET. N. Y., June 16, 1880.

INCOMPETENT DRUGGISTS.

To the Editor of The Medical Record.

DEAR SIR:—I have seen in your paper sundry articles on druggists, with hints how to remedy the evil. That the incompetency of certain druggists is a source of great trouble to some physicians cannot be doubted. The physician orders a certain combination from which he expects certain results; the druggist misreads the prescription, and the doctor is disappointed with the action of the medicine. While the medicine may do no harm, it does not do the good intended. I call to mind a case in my practice, where I ordered a mild, unirritating mixture. What the druggist put up I know not, but every time the medicine was given to the child, what little escaped the mouth raised a blister wherever it touched. The result was, the mother took the child to another doctor; he prescribed (according to the mother's statement) about the same thing; she had the medicine mixed by the same druggist, and it, too, acted the same. He then gave the same prescription and sent her to another store, where the medicine was compounded correctly, and obtained the result desired. Later she brought the patient back to me, convinced that I was not to blame, but the druggist. During the night of May 31st, I sent the following prescription to a drug store on Broadway, above Seventy-first street:

℞. Tr. opii camph.................. ʒ iv.
Potas. nitratis................. .... ʒ i., ℈ iv.
Syr. tolutan,
Aq. cinnamon, āā ad .... ℥ iv.
M. Sig.—Tablespoonful every two hours.

I asked to see the medicine the next day, and was dumbfounded to find an eight-ounce mixture. I learned, on inquiry, that the druggist refused to get out of bed, and his wife put up the medicine. I called on the druggist and remonstrated with him for his error; he said to me: "What does that *ad.* stand for? we have no *ad.* in German." He tried to convince me that I had written for an ℥ viii. mixture, and when I insisted that it read plainly an ℥ iv. mixture, he kindly informed me that I was a fool. He said: "What is it for?" I told him, "None of your business." "You prescribe nitre for a cough, you're no doctor," etc. And when I insisted he had made an error, he ordered me out of his store. The remedy for all this has been suggested in your journal, viz.: to put up your own medicine. I can attest the value of this, for I have been preparing my own drugs for nearly two years. I find that patients like it much better, and I have obtained better results. In mixing your own medicines, you know that patients receive what you want them to have, as also the full quantity. The trouble is no excuse. Let the physician furnish the laboratory, and, if too busy to mix the medicines himself, hire a competent man, and know what the patient is taking. Any one who will try this plan will be more than gratified with the results. It is now time that physicians take this matter in hand, and render all further complaints against druggists unnecessary.

Respectfully, * * *

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 20 to June 26, 1880.

The following promotions and appointments are published:

Lieut.-Colonel W. S. King to be Surgeon with the rank of Colonel.

Major John E. Summers to be Surgeon with the rank of Lieut.-Colonel.

Asst. Surgeons Wm. E. Waters, Edwin Bentley, Geo. A. Otis, and Geo. P. Jaquett to be Surgeons with the rank of Major.

Rudolph G. Ebert, of Oregon, Robert J. Gibson, of Connecticut, Robert B. Benham, of Pennsylvania, Wm. C. Gorgas, of Alabama, Norton Strong, of Michigan, and Arthur W. Taylor, of New York, to be Assistant Surgeons, U. S. Army.

Cronkhite, H. M., Capt. and Assistant Surgeon. Granted leave of absence for two months. S. O. 134, A. G. O., June 18, 1880.

O'Reilly, R. M., Capt. and Assistant Surgeon. Granted leave of absence for one month on Surgeon's certificate of disability, with permission to leave the department. S. O. 73, Dept. of the South, June 18, 1880.

DeLoffre, A. A., Capt. and Asst. Surgeon. Relieved from duty in Dept. of the South, and upon arrival in Dept. of the Missouri under present orders, to report by letter to Comd'g Gen'l of that Dept. for assignment to duty. S. O. 137, A. G. O., June 22, 1880.

The Death of Dr. Charles M. Allin.—The Board of Directors of the New York Eye and Ear Infirmary have heard, with regret, the announcement of the death of Dr. Chas. M. Allin.

His relations to the Infirmary began in 1852, when, for two years, he did duty as surgeon. He removed from the city and was not again connected with the institution until 1865, when, for three years, he acted as assistant-surgeon, and in 1868 he was made surgeon, and also entered the board of directors as director ex-officio. In 1869 he was appointed secretary to the board, and in 1875 he resigned his position as surgeon. The board then chose him to be a director, that he might legally retain his office as secretary, and in 1876 he was made consulting surgeon. In 1879 he was compelled, by the illness which ultimately terminated his life, to retire from the position of secretary, which he had held with great ability for ten years. At the time of his decease he remained one of the consulting surgeons, and also a director of the institution. Dr. Allin has thus fulfilled duties in the Eye and Ear Infirmary, of an important character, for eighteen years.

It was characteristic of him to be prompt, exact, careful, and cheerful in all his work. He fulfilled to the utmost his duty to the patients under his care, and in his office of secretary he was painstaking and precise. His courtesy and affable demeanor made his presence always welcome, and his intelligence rendered his opinions valuable.

The board, therefore, unite in the following resolution:

Resolved, That the directors express their sincere grief at the death of their late associate, Dr. Chas. M. Allin, who has been taken away in the prime of life from most useful activity in this institution.

They hereby record their sense of his worth and charm as a man, of his skill as a surgeon, and of his efficiency as a director and secretary to this board.

They recognize the debt which the institution owes to his long and laborious and faithful services.

Resolved, That the board respectfully offer to his family the assurance of their true sympathy, and that they share in their bereavement.

Resolved, That a copy of these resolutions be sent to the family of Dr. Allin, after being duly attested by the secretary and president, and be recorded on the minutes.

Benj. H. Field, *Vice-President.*
Richard H. Derby, *Secretary.*

Rhode Island Medical Society.—Annual Meeting, June 9, 1880.—The Society, to the number of eighty, convened Wednesday morning, June 9th, at Lyceum Hall, Providence. Dr. E. T. Caswell presided. Dr. Bullard, of North Attleboro, was present as delegate from the Massachusetts Medical Society.

The report on the Fiske fund showed that a prize of $200 had been awarded to Dr. Charles V. Chapin, of Providence, at present "house physician" in Bellevue Hospital, New York, whose essay on "The Sympathetic Nerve and its Relation to Disease" was pronounced to be of unusual merit. For 1881, a prize of $150 is offered for the best essay on either of the following subjects: "The Action of Medicines in the Cure of Diseases," and "Uterine and Ovarian Diseases as a Cause of Insanity." The Library Committee reported favorably as to increase in number of volumes and amount of money subscribed. It is hoped that an annual subscription of $600, and a building fund of $20,000 may be obtained. Nearly one thousand volumes have been collected. The report of delegates to the New York convention of the American Medical Association was highly commendatory. The committee appointed at the last quarterly meeting to consider the protection of physicians in the matter of "Expert Testimony," and also "The Regulation of the Practice of Medicine and Surgery," reported unfavorably so far as legislative action is concerned. Charles V. Chapin, M.D., George L. Wood, M.D., and Charles D. Albro, M.D., were made fellows of the Society.

The following officers were elected: President, Charles O'Leary, M.D., Providence; 1st Vice-President, Job Kenyon, M.D., Providence; 2d Vice-President, O. C. Wiggin, M.D., Providence; Recording Secretary, V. O. Hardon, M.D., Providence; Corresponding Secretary, E. M. Harris, M.D., Providence; Treasurer, C. H. Leonard, M.D., Providence. Dr. W. O. Brown, of Providence, read a paper entitled "A Study of Atmospheric Changes, as Influencing Health," in which it was claimed (1), that the lower animals are manifestly sensitive to atmospheric conditions; (2), chronic diseases, especially those of a neuralgic nature, are directly modified by the same, and that most pain is suffered on the *fall* of the barometer, or just *preceding* it; (3), epilepsy and chorea are most severe at certain seasons; (4), that the relationship of ozone to disease, whether causative, curative, or preventive, affords an interesting field for investigation; (5), that the inhalation of oxygen gas has unmistakable therapeutic value, eight gallons per diem being a safe quantity; and (6), that electricity is an important factor in modifying health.

The annual address of the retiring president, E. T. Caswell, M.D., on the subject of "Public Health as Provided for by Legislation," was excellent in every particular. It embodied an earnest plea for the establishment of State Boards of Health, which should not be mere figure-heads, but comprise men thoroughly educated in sanitary science. The annual dinner was served by Mr. G. M. Ardoene, at the Hotel Dorrance. Dr. George H. Kenyon, of Providence, was master of ceremonies. Hon. Abraham Payne, President Robinson, of Brown University, and Rev. Dr. E. G. Taylor, were present as invited guests. The occasion was in every way enjoyable.

Death of Dr. James C. Hall.—Dr. Hall died at his residence in Washington, D. C., June 7th. He was born in Alexandria, Va., July 10, 1805. Graduating in letters at Jefferson College, and in medicine at the University of Pennsylvania, he went to Washington in 1828 and began the practice of medicine. He had considerable means, and took an active interest in the affairs of the city. In 1830 he was appointed professor of surgery in the Columbia University. He became a member of all the medical societies of the district, and before many years stood at the head of the profession in that locality. Dr. Hall was a man of wide knowledge and ripe culture. His acquaintance with the classics was remarkably thorough, and was kept up till his old age. During the latter part of his life his failing health obliged him to give up very active practice, but he always kept himself thoroughly informed on the advances in medicine, and his services as a consultant were in great demand. Dr. Hall had the social qualities which win friends, and he leaves many to mourn his loss.

A Remarkable Case of Gastrotomy.—Dr. G. H. Boyland, of Baltimore, relates, in the *Boston Medical and Surgical Journal*, a very novel case of twin pregnancy and gastrotomy. The patient, aged twenty-two, was pregnant, for the fourth time, with twins. She had three living healthy children. She was confined in normal labor April 15th. From the appearance of the child, and the statement of the mother, it was believed to be born about one month before its time. The child lived. Subsequent to this, Dr. H. P. C. Wilson, who attended the case, by physical examination, concluded that there was another child in the abdominal cavity. Exactly three weeks and five days after the birth of the first child, he delivered, by abdominal section, the second child, a healthy boy, still living. The operation was that of gastrotomy, in technical distinction from Cæsarian section, the incision beginning three inches above the umbilicus. It was performed under Lister, and carried out in every detail. The child was found in a sac filled with about half a gallon of serous fluid. The placenta occupied the left half of the brim of the pelvis, and was composed of three distinct portions, being attached to the left side of the uterus, the left Fallopian tube, and the top of the left broad ligament. The woman lived ninety hours after the operation. There were no symptoms of pyæmia, septicæmia, or peritonitis. The woman had been cheerful and comfortable. She asked the nurse to raise her in bed; this was done, when she suddenly turned livid and died. The cause of death was probably embolism. Nothing was found to explain it at the autopsy.

Commencement at Long Island College Hospital.—The twenty-first annual commencement exercises of this college took place at the Brooklyn Academy of Music, June 23d. Forty-five students were graduated. The president of the collegiate department presided and conferred the degrees. Mr. R. W. Ropes, of the Board of Regents, opened the exercises, and in doing so said that the Long Island College Hospital had now reached its majority—its twenty-first anniversary. The city was deeply indebted to those who originated this college, which is now one of the finest in the country. Only once in the history of the institution had a larger class been graduated. Prayer was then offered by Rev. John D. Wells, D.D. The names of the graduates were read by Dr. Jarvis S. Wight. After conferring the degrees, an address was delivered by Rev. James M. Buckley, D.D., who was listened to with marked attention and was repeatedly applauded.

The prizes were awarded by Dr. Samuel G. Armor, Dean of the Faculty, after which a popular air was performed by the band. The exercises of the evening were brought to a close by Glen R. Butler, M.D., who delivered the valedictory.

A Convalescent Hospital is to be established in connection with the Massachusetts General Hospital, says the *Boston Medical and Surgical Journal.* Through the energy of a Boston lady, Miss Mary Russell, a fund has been started which is already large enough to authorize the trustees to begin the erection of a suitable building in the suburbs of Boston.

Hygiene and House-Plants.—According to Dr. J. M. Anders, in the *Philadelphia Medical Times*, the popular idea that house-plants are unhealthy things for sleeping and sick rooms is not correct.

The chemical changes which they cause in the air are insignificant. Their principal effect is to throw off moisture which is often beneficial. As a result of a number of inquiries among gardeners and florists, Dr. A. considers it probable that living in a room where there are plenty of plants has a certain prophylactic effect against phthisis, for those predisposed to it.

In a room of average size, say 20 × 16 × 12 feet, a dozen thrifty plants are enough to keep the moisture at a healthy standard. These plants should not bear flowers with heavy perfume, but should have soft, thin leaves, with extensive leaf-surface.

Drug-Stores in Philadelphia.—There are over seven hundred drug-stores in Philadelphia, says the *Reporter*, and not one of these could exist on its legitimate business of compounding prescriptions. The superfluity of drug-stores is due to the profits of patent medicine and counter-prescribing.

Yellow-Fever at Quarantine.—The second instalment of yellow-fever cases reached this city June 24th, on an Austrian bark. The vessel had come from Port de Paix, Hayti, and was bound for Boston. The entire crew were attacked with the fever, however, and were obliged to put into this port. When the vessel reached New York only the mate and a boy were well enough to navigate the ship. The captain and one of the crew had died; six others of the crew were reported to be in a precarious position.

Dr. R. J. Jennings of Arkansas. — The name Dr. R G. Young, of Arkansas, on page 640 of The Medical Record, should have been Dr. R. J. Jennings, of the same place.

A Plea for Chloroform.—Dr. A. G. Smythe, of Baldwyn, Miss., writes: Will you be so kind as to permit a backwoods general practitioner, and regular reader of the Record, to protest against the summary conviction and capital execution of chloroform as proposed in a recent number of the Medical Record, by your Milwaukie, Wis., correspondent. While I am and have all my life been only a general practitioner, most of the time in the country, and cannot marshal surgical cases by the thousands, yet I propose to offer a few facts that have come within my own knowledge.

At the outset it will be admitted that chloroform is a potent agent, and should be used with the utmost caution and prudence, the routine description of which will be supposed to be well known to your readers.

Immediately after the publication of the success of the administration of chloroform by Sir James Y. Simpson (say, as early as January, 1848), I procured a small quantity, with which I experimented upon myself in all the ways that I could without an assistant, and discovered that it almost invariably caused nausea and vomiting if taken a short time after eating. As early as February in the same year (1848), I administered it to a small boy, aged eight years, without any assistant or any person being present, and sucessfully performed a tedious and painful minor operation in the mouth, entirely free from pain or any untoward circumstances. (Will not give it in operations upon the nose, mouth, or throat, at present—it is not safe.) From that day to the present time have used it—as all therapeutic agents are used by myself, with prudence, paying but little attention to the host of so-called contraindications, except in the operations parenthesized—in a large number of capital, and a host of minor operations in surgery, also in general practice; in at least one thousand and four hundred, out of two thousand and six hundred cases of obstetrics, without a failure in a single case. Only in four cases were there any symptoms to cause alarm on the part of those present, and but two that caused solicitude to your contributor. There is no agent in the whole materia medica with which your contributor has had such uniform success as that of chloroform, having at no time in thirty-two years failed to obtain all that was anticipated when it was given. No mortality (not a single case), where chloroform could be charged with any agency in causing a fatal result. There is no other remedy (not even quinine, and I have but few charges against it), which has been given to the same extent, that has given such entire satisfaction as the one in question. And now, at this late day, to presume to summarily dismiss a remedy which has passed through such an ordeal, and that can muster an array of friends and vouchers who, in point of character, skill, and numbers, would strike consternation to the enemies of chloroform, the proposition as made by your contributor is, to say the least, summary and premature. Give chloroform and its friends a hearing; raise a committee or commission of investigation. The friends of chloroform do not fear a fair investigation.

In the future there may be discovered (I trust there will be) a safer and more pleasant anæsthetic than chloroform; but that it has been done up to the present time is doubted by a very large and respectable number of the profession throughout the civilized world.

Did time and space permit, much might be urged in this article as to the mode of administering chloroform, as compared with other remedies of the same class. Being more active in its action, it should be given slower, is all that will be said at present.

As an apology to your readers, will say that your contributor is by no means as young as he has been, and is at present almost blind; but was determined to come to the rescue of chloroform; not, however, that he had any fears that it would be dismissed from the Materia Medica.

Original Communications.

TRACHEOTOMY IN CROUP:

WITH REMARKS ON

THE PATHOLOGY, DIAGNOSIS, PROGNOSIS AND TREATMENT OF THE DISEASE, AND THE CAUSES OF DEATH IN FATAL CASES; WITH A REPORT OF THIRTY-FIVE OPERATIONS.

By JOHN H. RIPLEY, M.D.,

SURGEON TO CHARITY HOSPITAL; PHYSICIAN TO ST. FRANCIS'S HOSPITAL, NEW YORK CITY.

PART II.

CASE XIV.—Isabella McG——, a strong and previously healthy girl, six years old, returned from school Dec. 21, 1874, complaining of a severe chill, which she attributed to sitting by an open window during the afternoon. In the evening she had high fever, which continued through the next day (Dec. 22d).

I saw her in the evening about five o'clock. She was able to be about the room, but preferred to lie on the sofa most of the time. Her countenance was flushed, neck swollen, and a profuse, offensive, purulent discharge was issuing from the anterior nares, which, the mother said, began the previous afternoon. On examination, I found the fauces and tonsils congested and swollen, but no membrane was seen on these parts or in the anterior nares. Temperature, 103°; pulse, 162; respiration, 40. A solution of chlorate of potassa and tincture of iron was ordered.

Dec. 23d. General appearance better. She arose at her usual hour and has remained up. The tonsils are still large and red, and on the internal face of either is a large patch of loosely attached membrane. In fact, that on the left side hangs only by a border, and is easily removed with dressing-forceps. Pulse, 152; temperature, 100.5°; respiration, 22.

24th, 10 A.M.—The swelling of the neck has greatly increased since yesterday, especially on the right side, and the child sits in a low chair with the head thrown back, mouth open, breathing laboriously and showing little disposition to talk or notice objects about her, although she is not cyanotic nor drowsy. The nasal mucous membrane is so swollen as to nearly close the passages, and the ichorous discharges therefrom have produced erythema and tumefaction of the central portion of the upper lip. The isthmus of the fauces is nearly obliterated from infiltration of the soft parts bounding it, and both the uvula and tonsils are encased in thick, dirty grayish membrane. Pulse, 140; temperature, 100¼°; respiration, 22. 7 P.M.—Child has been drowsy all the afternoon, and great difficulty has been found in administering food and medicine. She is now lying on the sofa asleep, breathing noisily through the widely opened mouth, from which also the saliva is constantly drivelling. I syringed out the nasal passages with a solution of salt and water, but it did not afford much relief to the respiration, and some bleeding followed from the left nostril. The patient was quite exhausted after the operation and immediately fell asleep.

25th.—Patient is up again and looks quite bright. Her mother says she began to improve about midnight. Her pulse, however, is very rapid—150—and she has vomited her food and medicine several times since my last visit. She has also a slight cough of a perceptibly metallic quality. 4 P.M.—Laryngeal obstruction is now manifest. The respiration is stridulous, and there is recession of the epigastrium with each inspiration. There is yet no visible cyanosis, but the girl is very drowsy. Pulse, 120; respiration, 18. Tracheotomy was proposed and consented to by the parents. Returning an hour later and finding the breathing better and the child brighter, the operation was postponed. At 10 o'clock in the evening the croup symptoms had become so grave that it was decided to wait no longer. With the assistance of Dr. A. C. Graham and the late Dr. J. D. Rogers, tracheotomy was performed. The great tumefaction of the neck, the toxæmic and asthenic condition of the patient, combined to make the operation one of great difficulty and danger. Several times during its progress respiration became suspended, and we were compelled to stop proceedings and devote ourselves to restoring it. Finally, after the tube was in place, this movement had to be excited for several minutes by irritating the mucous membrane of the trachea with a feather before it became re-established. We left her breathing regularly and quietly.

26th, 10 A.M.—Swelling of the neck has increased and now involves the face, and the child is very lethargic. Several large pieces of loosened membrane were removed from the soft palate.

Beef-tea and champagne substituted for brandy and milk, as the latter are not retained by the stomach. Pulse, 144; respiration, 26; temperature, 101.°

27th, 10 A.M.—Parents report that last night she rallied, was very bright, took nourishment well and retained it, and subsequently passed a comfortable night. During the early part of this morning she seemed to be still better, and was playing with her father, sitting up in her crib. About an hour ago her mother noticed a marked change: her lips were blue, her extremities cold, and she was very restless. These symptoms were present when I saw her, and, in addition, the radial pulse could not be felt. I gave an enema of half an ounce each of brandy and strong green tea. The pulse rallied again for about half an hour, then disappeared, and she died quietly at 1 P.M. A brother and sister, the one younger and the other older than she, were attacked with a mild form of naso-pharyngeal diphtheria about the time of her death, and both recovered.

CASE XV.—French girl, three years and four months old, had been sick five days with naso-pharyngeal diphtheria, when I first saw her with Dr. Milne, the attending physician, April 19, 1878. Croup had set in on the 17th, and was now in an advanced stage. There was loud stridor, frequent suffocative attacks, cold extremities, livid face, and commencing coma. The swelling of the neck was slight; membrane in the anterior nares and on both tonsils. Respiration, 42; pulse, 160; temperature, 100.5°. A full dose of brandy having been given, tracheotomy was at once done, under chloroform, Drs. Milne and Daniel Lewis assisting. Just as we reached the trachea, the respirations suddenly became shallow and then ceased. An opening was at once made and the tube introduced, when voluntary breathing immediately began, and continued without further accident.

April 20th, morning.—Child has an anxious countenance, is very irritable, and the discharge of purulent matter from the tube is profuse. Pulse, 100; respiration, 40; temperature, 101¼°. Evening.—No marked change.

21st, morning.—Pulse, 138; respiration, 38; temperature, 101°. Evening.—Pulse, 150; respiration, 44. General appearance worse. The surroundings of this patient are bad. The people are very poor, and the father takes no interest in the child, while the mother has two other small children to care for, the youngest also sick with diphtheria.

22d.—Better. Breathing free, countenance good, and a disposition to eat. Pulse, 124; respiration, 38; temperature 101⅛°. Tube was changed for a clean one of the same size. While the change was being made the permeability of the larynx was tested by placing the finger over the external wound. The child immediately got blue in the face and struggled for breath, while little, if any, air was inhaled.

23d.—The patient is still improving. The cough and expectoration are quite moderate, but there has been some free hemorrhage from the trachea since yesterday, although not sufficient to demand treatment. Temperature, 99.4°; pulse, 130; respiration, 38.

25th.—Convalescent. Temperature, 98.5°; respiration, 32; pulse, 124.

29th.—Child playing about the room. An attempt was made to permanently remove the canula, but there was still so much stenosis that it was considered safer to wait. A younger sister has died of diphtheria since my last visit, and an older sister is still sick of the same disease, but not dangerously.

May 30th.—The tube was left out on May 2d, and the wound treated with a little balsam and oakum. Recovery complete, and no secondary paralyses.

Case XVI.—Dr. F. B. Strickland sent for me November 22, 1876, to operate for croup on a little boy three years and nine months old, who had been sick a week. The symptoms, until two days previous, had been those of an ordinary naso-bronchial catarrh. On the evening of the 20th there was a little hoarseness, but the next morning it had mostly disappeared, and the child played about the house as usual. In the evening again it became worse, obstructive laryngeal stenosis developed during the night, and steadily progressed until I saw him. When first seen by me he was lying with head thrown back and mouth wide open, breathing stridulously and with great difficulty. The characteristic supraclavicular and epigastric retractions took place during inspiration. Pulse, 130; temperature, 100°. The internal surface of either tonsil was covered with a grayish-white membrane. No swelling of neck. The trachea was opened at once, Drs. Strickland and Hawes assisting. Nothing noteworthy occurred during the operation. No membrane was seen in the trachea. The relief from dyspnœa was complete.

23d, 3 P.M.—The boy has had a quiet night and a comfortable day, but does not take nourishment well. The membrane on the tonsils is partially detached, and there is no new deposit. There is a free muco-purulent discharge from the nose, but we are unable to see any membrane in the passages.

24th, 11 A.M.—General appearance good. Tongue moist and natural, and less membrane on the tonsils. The neck in the region of the wound is red and somewhat swollen, and the discharge from the tube is profuse. Pulse, 138; respiration, 28; temperature, 100°. Urine examined with negative results.

25th, 11 A.M.—The boy is playing with his toys, but the increased infiltration of the neck, gaping wound and "sawing respiration" do not look encouraging. Membrane has almost entirely left the tonsils, and the tongue is moist and clean. Several large pieces of membrane have been coughed up since yesterday. Pulse, 136; respiration, 26; temperature, 100.°

26th, 11 A.M.—The neck is enormously swollen, the wound of a dark red color, except certain portions which are covered with a thick membrane. The respiration is sawing, the face cyanotic, and there is a constant harassing cough which is evidently aggravated by a loosened piece of membrane either far down in the trachea or in one of the larger bronchi. The lungs are clear. Attempts were made with forceps, with probang, and by pouring lime-water into the trachea, to relieve the dyspnœa and dislodge this membrane, which flapped to and fro with each respiration; but we did not succeed, and only exhausted the child. Finally, the tube was left out altogether, and the parents instructed to see that the boy did not get his neck twisted and thereby produce asphyxia by closure of the wound. Some slight amelioration of symptoms temporarily followed, but death took place about midnight, the temperature rising, meantime, to 103°. A little brother was taken about the time of his death with croup symptoms, but recovered. The doctor attributed the favorable termination to frequent spraying of the parts with a twenty-grain solution of acetic acid. A solution of chlorate of potassa and tincture of iron was given internally to the other child, and no local treatment, except a moist sponge kept over the opening.

Case XVII.—Sept. 7, 1877, I saw, for the first time, M., a boy four years old, who had been taken sick in the country three days before, while temporarily residing with a family where several children were sick with sore throat. His symptoms were at first attributed to a cold, but the day before I saw him he developed a croupy cough, which so alarmed the father that he at once started for the city with him, arriving late the same evening. During that night the symptoms progressed, and he had several severe attacks of dyspnœa. In the morning he had a severe suffocative attack, and I was sent for. When I reached the house the attack had subsided, but the symptoms were still urgent. The voice was husky, the lips cyanotic, and the veins of the neck turgid. Each stridulous inspiration was accompanied by marked supraclavicular and epigastric retraction. The boy was drowsy. Pulmonary percussion was generally tympanitic. The glands of the neck were of normal size and the fauces of natural appearance, except a small patch of membrane on the left tonsil. Temperature, 101⅘°; pulse, 92.

Tracheotomy having been consented to by the father, Dr. Hawes administered chloroform without delay. The operation was especially easy, and the hemorrhage trifling; vomiting occurred soon after the tube was in place—probably from the effect of an emetic of squills and ipecac, which had been given just before my seeing the child—and respiration ceased. After irritating the trachea through the canula with a feather, the breathing started again and all went on well. The breathing was perfectly free and noiseless, and auscultation of the chest, a few hours afterward, showed that air entered the lungs freely at all points. The following morning I left the city and did not see the child again until the 14th. Dr. Hawes, with whom I left the case during my absence, removed the tube on the 12th, although there was still a good deal of stenosis of the larynx; but the wound of the soft parts leading down to the tracheal opening was gaping and covered with membrane, and he thought that before this would close the larynx would have become sufficiently patent. The temperature had remained at about

100° during the week of my absence, and the respirations nearly normal. The bad temper of the boy had prevented the doctor from getting him to take any medicine; in fact, he was with difficulty induced to take nourishment. On my return I found his general condition good, but the wound was still unhealthy, sloughy, and covered with a thick, dirty yellow membrane, and the odor from the parts was very offensive. This membrane—portions of which I showed to Prof. Delafield and Dr. S. Whitall—contained little *lacunæ*, apparently formed by the breaking down of its structure, in which were myriads of both the spherical and rod-shaped bacteria, the latter form most numerous.

19th.—The wound to-day, for the first, presents a healthy appearance. Since my last note the membrane has been peeled off daily, but as often reformed; now, however, there are only a few small patches, and the red, swollen appearance has given place to healthy, rose-colored granulations.

21st.—The child is rapidly improving, and has a good appetite. Respiration is carried on entirely through the larynx, and the voice is clear.

23d.—Only a small granulating surface now exists, which is on a level with the surrounding healthy integument.

Oct. 13th.—The patient was discharged two weeks ago, having only a little general bronchitis, for which cod-liver oil was ordered. If any paralysis of the vocal cords occurred in this case, it must have been present during the second and third weeks of the disease, and was the cause of the hoarseness; certainly, none was observed later.

It is remarkable how small a cicatrix remained after so large and protracted a wound, especially as there was considerable loss of tissue.

Case XVIII.—August 18, 1878, I was called to see F. S——, two years and four months old, who had been ten days under the care of Drs. Burton and Spor for naso-pharyngeal diphtheria. There had been a slight degree of hoarseness for a week past, but no laryngeal obstruction until the day before I saw him, when croup developed and had been steadily progressing since. The symptoms now were: flushed face, toneless voice, epigastric depression on inspiration, which act, as well as expiration, was accompanied with stridor; drowsiness, membrane in pharynx and nose, etc., a sanious discharge from both nostrils, absence of respiratory sounds on auscultation. There was no infiltration of the tissues of the neck. Tracheotomy. Drs. Burton, Spor, Milne, and Crenshaw present and assisting. No complication or accident during the operation. No membrane seen in the trachea. Complete relief. Air enters the lungs freely. Seven hours later, temperature, 102¾°; respiration, 40; pulse, 150. There was ordered bromine, gr. j., every two hours, alternating with milk-punch.

19th, 8 A.M.—Boy has rested well through the night and looks bright. Temperature, 100⅝°; respiration, 36; pulse, 114. 10½ P.M.—Cough has been troublesome during the day, but I find nothing abnormal in the lungs but mucous râles. Several pieces of membrane have been expelled through the tube since my last visit, one of which about a quarter of an inch square is shown to me. He has taken only three doses of the bromine, "because he don't like it."

20th, evening.—Child has been playing with his toys nearly all day. An abrasion of the chin is covered with membrane. Temperature, 101⅘°; pulse, 120; respiration, 32.

21st.—The tube was temporarily removed this morning, when great dyspnœa immediately ensued and the child became cyanosed. The cause of this was evident when I saw within the trachea a large piece of detached membrane being forced into the tracheal slit with each expiration, and again drawn downward, obstructing the entrance of air with the succeeding inspiration. It was easily extracted with my forceps, and measured one and one-half inches in length, was cylindrical and bifurcate at its smaller extremity. Several smaller pieces were also coughed up. Little air could be obtained through the larynx, and no voice-sounds. About mid-day, after playing with his toys for an hour, he suddenly fell back upon his bed, his breathing became slow and gasping, and his face assumed a deathly pallor. I was sent for at once, but before my arrival the danger was past and the boy sleeping. I gave him a full dose of brandy, after which he again slept for four hours and remained listless the remainder of the day. Morning temperature, 100°; respiration, 26; pulse, 126. Evening temperature, 99½°; respiration, 30; pulse, 100. Bromine has been given with tolerable regularity every four hours, and is to be continued at intervals of six hours. No local applications have been made and no steam used.

22d.—Boy bright and symptoms favorable. Temperature, 99½°; pulse, 120; respiration, 30.

23d.—The perviousness of the larynx is not yet sufficient to do away with the tube. The wound of the soft parts has healed throughout by first intention. Temperature, 99½°; respiration, 24; pulse, 120.

From this time on, the progress to recovery was uninterrupted. The canula was permanently removed on the 26th, and the wound of the trachea closed a few days later. No paralysis of any kind followed, so far as I know.

Case XIX.—February 14, 1877, Dr. S. S. Jones asked me to tracheotomize B——, a little girl two and a half years old. The case was all but hopeless at the time of the operation—a complication of scarlet fever, diphtheria, and broncho-pneumonia, with a temperature of 106°. The stenosis was not very grave, except during certain spasmodic attacks, when her efforts to get air were very distressful. It was to relieve these painful symptoms that we consented to do the operation; for, in this instance, the parents insisted on having tracheotomy done. Drs. Whitall and Jones assisted, the former giving ether. This anæsthetic gave us much trouble in its administration, aggravating the laryngeal trouble to such an extent that we could only let her inhale a few whiffs consecutively, and then withdraw it for a few seconds. Fortunately she was quickly anæsthetized and the operation a very simple one. The suffocative attacks were relieved, but the pulse and respiration continued frequent, and she died about six hours after the operation. Another child of the family had uncomplicated naso-pharyngeal diphtheria the same week, but recovered.

Case XX.—W——, æt. three years and one month, complained of stiff neck, Nov. 1, 1878, but the following day was better, and continued apparently well until the 5th, when croupy cough was observed by the father. On the 6th he ate and played as usual, and the hoarseness had disappeared. On the 7th hoarseness was observed in the morning, continued through the forenoon, and became worse in the afternoon, after his noonday nap. At 3 P.M., when I saw him, there was croupy cough, flushed face, and some little dyspnœa. The glands at the angle of the jaw, on both sides, were enlarged, and the neck a little swollen; the tonsils large, red, and covered with membrane. No nasal discharge, nor any membrane to be seen in the passages. Pulse, 140; temperature, 101°; respiration, 28. Hot poultices were ordered to be applied to the neck, and a grain of bromine to be taken internally every two hours. By 9 P.M. the dyspnœa had greatly increased and the child was becoming restless and cyanotic. Tracheotomy was performed half an hour later, Drs. Geo. F. Shrady and Chas. Milne assisting. Owing to our having insufficient light, a medium-sized vein was accidentally cut during the operation, and required ligature. Marked relief followed the introduction of the canula, but the respiration continued rapid.

8th, 12 M.—Temperature, 104°; respiration, 58; pulse, 160. Breathing noisy. Boy lies with closed eyes, and does not like to be disturbed.

9 P.M.—Pulse, 144 (weak); respiration, 56 (and noiseless); steam from a croup-kettle has been constantly inhaled since noon to-day, and has certainly improved the breathing. A peculiarity of this case is that there has been very little secretion from the air-passages, and very little cough. The swelling of the tonsils has diminished and the membrane nearly all disappeared. Infiltration of cervical tissues remains about the same.

9th, morning.—Child has had a good night, and looks somewhat better. Temperature, 101°; pulse, 144; respiration, 38. While changing the canula for a longer one, spasmodic cough was excited, during which a small, tubular piece of membrane, over an inch long, and having a circular opening about midway between its extremities, evidently from one of the bronchi, was expelled through the tracheal opening. In the afternoon the breathing grew more harsh and rapid, and the pulse more frequent and feeble, although the temperature still remained at 101°. A physical examination revealed almost entire absence of respiratory sounds—in fact, there was comparative absence of all sounds, while the percussion note was generally tympanitic.

10th, 10 A.M.—Throughout the night the patient suffered much from dyspnœa, "clutched at his throat" in vain efforts to get relief, and was only prevented from pulling the tube out by continuous watching. The face is now cyanotic, and the usual signs of obstruction to the entrance of air into the lungs are visible on inspection. Temperature, 97½°; pulse, 150; respiration, 42. Steam has been constantly inhaled and bromine regularly given since the 7th. Died at 1.30 P.M.

CASE XXI.—G——, a nursling, eleven months old; rachitic, large fontanel, no teeth, "pigeon breast," bow legs. Had been sick three days, with what at first was thought to be an acute laryngo-bronchial catarrh. On June 24, 1878, she developed a croupy cough. On the morning of the 25th, when I saw her with the attending physician Dr. Geo. Schlereth, there was some huskiness of voice, moderate dyspnœa, and a rectal temperature of 102°; no swelling of the submaxillary or cervical glands, no abnormal appearance of tonsils or fauces, and no membrane visible anywhere. We ordered hot poultices to be applied over the larynx, and agreed to see the patient again in four hours. When we returned grave dyspnœa existed, and the voice was entirely lost. With the assistance of Dr. S., I performed tracheotomy; easily and without accident. A large piece of membrane, a partial cast of the trachea, was coughed up through the tube soon after the operation. The relief was only partial.

26th.—Temperature, 103½°; respiration, 60; dyspnœa as great as before the operation. Lungs generally tympanitic on percussion; mucous and dry râles heard on auscultation; loss of respiratory murmur. Died the same day. Permission was granted to examine the trachea and larynx only. Both were completely lined with a tough, adherent membrane, about one-sixteenth of an inch thick.

The treatment of the case consisted in the internal administration of muriate of ammonia and chlorate of potassa, and the inhalation of steam.

CASE XXII.—Dr. W. A. Hawes saw Hanlon, a boy four years old, who had had a loose, hoarse cough for three days. An examination of the lungs and throat gave negative results. A mixture of chlorate of potassa was ordered. He was sent for early the following morning because the breathing had gotten so much worse through the night. He found urgent laryngeal obstruction. The face was livid, the extremities cold, and each inspiration was accompanied with a loud, whistling sound and deep epigastric and supraclavicular depression. No membrane could be seen. The rectal temperature was 97 ; pulse, 160; respiration, 52. After obtaining the consent of the parents, he came for me to do tracheotomy. The thyroid body was large and the veins turgid, but we did not meet with any accident, and, after the canula was secured in place, the respiration became tranquil, although it remained rapid. The temperature was 99⅘°, and the pulse 120, ten minutes after the operation. The respiratory murmur was of low pitch and vesicular. At 3 P.M., eight hours after the operation, the temperature was 104.5°; pulse, 130; respiration, 60. Bronchial respiration was heard over the whole of the left lung posteriorly, and the percussion note was markedly dull. There were also signs of beginning consolidation of the right lung. The child was delirious. Poultices were applied to the chest and a febrifuge mixture ordered. He continued to get rapidly worse, however, had several convulsions, and died the same evening.

CASE XXIII.—Thomas N——, age three years and five months: having been sick several days with diphtheria, developed croup symptoms Dec. 18, 1878. Grave laryngeal stenosis rapidly supervened, and on the 19th Dr. Burton, the physician in charge, asked me to perform tracheotomy. At the time of the operation membrane was present on both tonsils, and a large strip on the posterior wall of the pharynx. There was no swelling of either the cervical or maxillary glands, and the boy's general condition was good. Temperature, 102⅗ ; respiration, 54; pulse, 172. Drs. Burton and Milne assisted me in the operation, which was uncomplicated. The relief was complete. Five hours later the respiration was 60, and temperature, 104°. Quinine, in five-grain doses, every two hours, was ordered.

20th, 10 A.M.—Passed a bad night. Breathing rapid and noisy; temperature, 103°; child apathetic. 6 P.M.—Temperature, 101.2°; respiration, 40; pulse, 130; respiration is noiseless and secretion from air-passages scanty. Child very thirsty. Quinine to be given every three hours, also milk and brandy. 21st, 10 A.M.—Slept well through the night. General condition good. Breathing easy. Temperature, 103°; respiration, 38; pulse, 118. 10 A.M.—Temperature, 101⅘ ; respiration, 38; pulse, 126. Has taken medicine and nourishment regularly through the day, and looks bright. His cough, however, is frequent and dry, and pouring tepid water into the trachea, with a view of expelling irritating matters from the air-passages, is unsatisfactory. Steam, evolved from a croup-kettle, was now constantly used until death. Mucous râles are heard on auscultation over the lower lobes of the lungs, but the respiration is vesicular and the percussion extra-resonant. The urine has been examined with negative results. The membrane has disappeared from the tonsils and pharynx. 22d, 10 A.M.—There is a marked change for the worse. The neck and submaxillary glands are swollen, the face cyanotic, the breathing rapid and labored, the cough frequent and feeble. Mucous râles are heard over both lungs, while over circumscribed areas on both sides there is comparative absence of all sounds—no bronchial breathing.

Percussion over certain portions is tympanitic, over others dull. Temperature, 102.5°. Several large pieces of membrane were pulled out of the trachea by means of long, curved forceps, but without relieving the patient. Died at 4 P.M. An older brother was just recovering from naso-pharyngeal diphtheria when this patient was taken ill.

CASE XXIV.—M. H——, a delicate girl, three years and eleven months old, who had suffered much from malaria for two years, was seized with a chill on the afternoon of November 28, 1878. This was soon followed by high fever (104°), lasting several hours, which terminated in profuse perspiration. A full dose of quinine (10 gr.) was now given, and the following morning (29th) another dose of five grains. In the afternoon she was drowsy and had some elevation of temperature, but no distinct paroxysm. During the ensuing night she took thirty grains of quinine and remained well the next day.

Dec. 1st.—She had slight fever in the afternoon. 2d.—In the morning she complained of sore throat, but on examination no evidence of local trouble was noticed. In the afternoon, however, while the father was giving her a pill, she became nauseated and had slight retching, during which the tonsils were fully exposed, and a patch of membrane was seen on the posterior surface of each. These parts were then thoroughly cauterized with nitrate of silver, and a grain of bromine ordered to be taken internally every two hours. 3d.—I was called to see her, and found her symptoms generally favorable. A small patch of membrane was present on each tonsil, that on the left being already loosened. The temperature was 101°, and there was no swelling of the neck or glands. The bromine was continued, but not with regularity, on account of its producing serious gastric irritation. 4th.—Symptoms still favorable. 5th.—Tonsils nearly free from membrane, but the uvula completely encased in it. Constitutional disturbance slight. 6th.—Membrane on uvula loosened, and a part easily removed with forceps. Some nasal obstruction, but no discharge, and no membrane to be seen. 7th.—Still appears to be doing well. 8th.—Last night, at midnight, she began to be hoarse and to cough croupy. The atmosphere was at once saturated with lime-steam supplied by means of several kettles filled with a mixture of quicklime and water and kept boiling. This treatment, however, did not appear to stay the progress of the laryngeal complication, for by 7 A.M. the following day the respiration had become continuously difficult, and attacks of suffocation frequent. At the request of the father, tracheotomy was done, Drs. Schoonover, S. S. Jones, and D. W. Perham assisting. The trachea was small, but easily reached, and without hemorrhage. No membrane was found within. The relief was complete. Eight hours after the operation she was doing well. Pulse, 120; respiration, 28; temperature, 100.2°. All medication discontinued except the steam.

10th.—Pulse, 96; temperature, 99°. Considerable muco-purulent discharge from both nasal passages, and membrane seen in the left nostril. A suppository of ten grains of quinine was given, but it was only retained half an hour, when the same quantity was administered by the mouth. 11th.—Temperature, 99°; breathing free. No membrane on the fauces, but it still remains in the left anterior naris.

12th.—Tube changed. Substantially, no air can pass through the larynx. Some bloody mucus coughed up during the day. Temperature, 98½°. 13th.—Small piece of membrane expelled from trachea. Doing well. 14th.—A severe attack of malarial fever began about 4 P.M. yesterday, and continued all night. The respirations became frequent, the pulse rapid, and a harassing cough set in, accompanied with a profuse discharge of pus and blood from the tube. Membrane has reappeared on both tonsils, and is also present in both nares. The patient is very feeble, and great difficulty is met with in administering food and quinine. The latter is not retained well, either by the stomach or rectum. The most successful method is found to be, to give large pills (10 gr.) at long intervals.

15th.—Improvement. No fever. Less secretion from trachea, and mostly mucus. She has had thirty-five grains of quinine since yesterday.

16th, evening.—Tube has been left out all day, but is to be replaced for the night. Membrane disappearing.

18th.—Tube was permanently removed yesterday. Some paralysis of the soft palate, and fluids occasionally fall into the trachea while the patient is drinking.

20th.—Wound in the neck is nearly closed.

From this time her recovery was rapid.

CASE XXV.—M., a boy, four years and eight months old, had a chill Aug. 17, 1879, which was followed by fever and delirium. The next day the constitutional symptoms were slight, and he was engaged in his plays as usual; but in the afternoon his mother saw "a white patch" on the right tonsil. Aug. 19th I was sent for, not because the child did not feel well, but the patch on the tonsil appeared to the mother to be a little larger, and, having lost a child the year previous from croup, she thought she would attend to this in time. I found the general symptoms mild, some nasal catarrh, but no membrane; maxillary glands a little swollen. Membrane was found on both tonsils. No laryngeal symptoms. In the evening hoarseness and a croupy cough developed. Large flaxseed-meal poultices, as hot as could be borne, were ordered to be applied over the larynx.

20th, 9½ A.M.—Pulse, 126; temperature, 100.8°. Cough croupy; voice husky. No apparent laryngeal obstruction. A three-grain quinine pill to be given every three hours.

21st, 10 A.M.—Better. Temperature, 100.2°; pulse, 120. Voice clear, but cough still croupy. The membrane on the right tonsil has increased, that on the left has disappeared. No discharge from the nose. Appetite poor.

22d, 2 A.M.—I was sent for because the child had been suffering from attacks of dyspnœa during the previous two hours. I found him sleeping, the respirations being accompanied with a rattling sound as of mucus in the larynx. On awakening him the breathing became noiseless, but the cough was metallic and the voice-sounds quite muffled. There was slight depression on inspiration in the suprasternal and epigastric regions. Temperature, 101.2°. The pulse was hard and wiry. There was also some catarrhal dysentery, which I attributed to the effect of a solution of chlorate of potassa and iron, which he had been taking in regular and large doses since the inception of the sickness. This I directed to be discontinued, and ordered an emetic of sulphate of copper. 10 A.M.—Pulse, 122; temperature, 100.9°; respiration, 18. The copper produced free and repeated emesis, but no relief, the obstruction remaining about the same. A well-defined milk-white membrane now lines both anterior nares; there is a small white formation on the pharynx, while that on the right tonsil has increased in size. 3 P.M.—Since my last visit the boy has had two very severe attacks of asphyxia, the face getting livid, and the patient "clutching at his stomach." The dyspnœa is now continuous and the countenance is flushed and anxious. Pulse, 140; respiration, 20; temperature, 101.8°.

As the symptoms became more and more urgent, tracheotomy was performed at 4.30 P.M., Drs. Robt. Milbank, Milne, and Spor assisting. A small vein was nicked during the operation, from which two drachms of blood, perhaps, were lost. A small piece of membrane was seen in the trachea after opening it, but it was sucked back into the air-passage, before it could be caught, and did not again appear. After the operation the breathing was free and noiseless. Pulse, 140; respiration, 26; temperature, 101.9°. 9 P.M.—Child looks well and takes food freely. A croup-kettle has been erected by the side of his crib, and is kept constantly boiling. Quinine, in two-grain doses, every two hours, is the only drug given.

23d, 10 A.M.—Pulse, 126; respiration, 26; temperature, 102.9°. Patient was restless and sleepless through the night, and was also very thirsty. Had frequent desire to go to stool, but has passed only small quantities of urine and fæces. Chloral and paregoric were ordered for the sleeplessness, which was thought to be due to uræmia.

9.30 P.M.—Pulse, 120; respiration, 32; temperature, 103°. The child is restless and the breathing a little noisy, but not labored. There is a moderate amount of secretion from the air-passages through the tube. A careful physical examination of the lungs discovers no lesion of their substance.

24th, 10 A.M.—Pulse, 120; respiration, 22; temperature, 103°. Sleeplessness was a prominent symptom through the night, although he took several doses of chloral and paregoric. He has frequent desire to go to stool and also to urinate, but the passages from the bowels are small, and consist mostly of partially digested food, while the urine is scanty and albuminous. His general appearance is good and he takes food well. The membrane neither increases nor diminishes.

10.30 P.M.—Pulse, 132; respiration, 26; temperature, 105.5°. Has passed no urine since morning, and there is none in the bladder. The countenance is of a leaden hue, the intellect clouded and the patient very restless. A bath (temperature, 70°) reduced the temperature one degree and improved his appearance for a little while, but he soon relapsed. Unstimulating diuretics were given and counter-irritants and hot poultices applied over the kidneys, but the suppression continued until death, which occurred at 4 o'clock the following morning.

(To be continued).

◆

Sea-water is to be furnished the inhabitants of London by the Great Eastern Railway Co. It is to be brought in in cans, and sold at the rate of sixpence for three gallons.

HALLUX VALGUS,

With a Report of Two Successful Cases.

By ALBERT N. BLODGETT, M.D.,

BOSTON, MASS.

A great deal of suffering among all classes of people is caused by the continuous and unvarying irritation and pain produced by comparatively trifling causes, which is borne without complaint, either because it seems too insignificant to be considered a disease and to be treated as such, or because there is comparatively little prospect of permanent relief from any treatment which can be employed in the case. No part of the body is more frequently the seat of these affections than the feet and the lower part of the leg, and probably no class of diseases is more rarely brought to the notice of the surgeon for treatment. The excessive degrees of these diseases are sometimes so serious in their character that the patient is brought into a frame of mind to endure any operative interference rather than suffer a continual martyrdom with no prospect of relief. It is one of the diseases of this nature which forms the subject of this paper.

The complaint to which I ask attention consists in the anatomical element of extreme abduction of the great toe, which, instead of forming a continuation of the line of the foot, is turned outward, is rotated upon its axis to a greater or less degree, and, in very marked cases, is found lying either *under* the other toes, or compressed into an irregular, deformed member, and crowded with the other toes, forming a conical projection from the line of the metatarso-phalangeal articulation. The other toes are adducted, that is, are inclined toward the middle line of the body, and therefore move in an opposite direction from the great toe. All the toes are therefore brought closely together and crowded one upon another, are altered in shape, and sometimes so constrained in their cramped position that they become anchylosed. The great toe shows a decided tendency to lie *under* the remaining toes, being found in the depression beneath the first phalanx, with the other toes closely folded down over it and turned downward, so that their points and the toe-nails rest upon the bottom of the shoe.

The degree of deformity which is produced by this disease is much greater than would be expected, and the disability which it occasions, both from its mechanical hinderance to locomotion, and from the intense pain with which it is often attended, is surprisingly great.

In connection with the distortion and dislocation of the great toe, there is generally much swelling and protrusion of the tissues about the head of the capitulum metatarsi, which is often the seat of intense suffering from pressure upon the prominent joint, which tends to aggravate the disease, and sometimes induces acute inflammation of the joint itself.

Prof. Hamilton considers the condition of the articulation to be that of subluxation, in which the first phalanx, instead of being simply dislocated outward, has partially rotated, so that its proximal end rests upon the outer surface of the capitulum. He also observes that the articulating surface is prolonged outward to a greater or less extent, to form a joint in the new position of the phalanx, and that the synovial cavity becomes obliterated at its internal border, both of which facts I was able to verify in the case I shall first report.

Here the articulating surface was displaced outward and downward, and was limited to an area of about six mm.

In regard to the causation of the disease in question, there can be no doubt that by far the larger number of cases are produced in a purely mechanical way, by the wearing of ill-fitting shoes. This effect may result from two causes: from shoes which are too narrow, and also from those which are too short. Of these two elements of causation in this particular disease, it would seem that pressure upon the ends of the toes, principally, of course, upon that of the great toe, would be the most frequent cause of the deformity in question. The great toe would be abducted to a powerful degree, while the other toes would be adducted, though to a much smaller degree. The continued action of a short shoe would serve to increase the displacement, and at length would crowd the great toe beneath the other toes and fold them down upon it, so that the ends of the smaller toes might rest upon the sole of the shoe. This is the condition called "hammer-toes," and is almost always present, to some extent, in cases of abduction of the great toe. Of course, the fashion of wearing high heels, now unfortunately in vogue among the ladies, has a continual tendency to produce or to perpetuate this disease, from the tendency of the foot to slide toward the toe of the shoe; and as if to furnish no chance of possible escape from trouble, many ladies' shoes are made with a so-called "box-toe," which does not yield to the foot, but compresses the toes as in a vise, so that some degree of deformity is nearly always induced by their continuous use.

Another cause which sometimes tends to produce abduction of the toe is any affection of the muscles which would shorten them, or in any way interfere with their functional integrity, thereby rendering them unfitted for their normal office. In some such conditions, abduction is the inevitable and necessary result, and in all there is great probability of its occurrence, as the consequence of an interference with the motor apparatus of a small and distant member, which is exposed to a continual tendency in the direction of the displacement. Of course, the primary disease of the muscles may be due to many causes which may be omitted here, since it is with the mechanical effects that we are now dealing. A third and frequent cause of the disease, is some lesion located in the joint itself, which causes a change in the shape of the capitulum, and often in the head of the phalanx as well. The articulating surface becomes displaced, so as to present no longer upon the end of the metatarsal bone, but rather upon its outer and inferior aspect, corresponding to which, the toe is swung around as on a pivot, and comes to lie in a direction nearly transverse to the line of the foot.

This condition may be caused by a periostitis, due to pressure of the boot, or to an injury to this region by an accident, and in either case forms a bursa, the so-called *bunion*, in which there is always swelling and pain in the tissues about the joint, and often a thickening of the bone in the vicinity, sometimes even an ostitis. Chronic arthritis is also a frequent cause of deformity in this joint, from the distortion of the articulating surfaces and thickening of the capsular envelopes which so often accompanies it. When the diseased condition is once established, the motions of the feet in walking, and the weight of the body, tend to perpetuate and increase the deformity. The muscles, when the toe is out of its normal line with the foot, draw upon the toe at an angle, and every contraction of the muscle tends to make this angle greater, thus, of course, increasing the distortion.

The distress occasioned by so painful a disease in a part continually exposed to pressure and weight, and the disability produced by the distortion of a part of the foot so important in locomotion, as well as the unsightly deformity which is produced by the displacement of the toes, all render any measure for the relief of this condition a boon to be eagerly sought for.

Various methods of treatment have been tried with varying degrees of success, but most of these have been discarded as impracticable or useless. Rest in bed will sometimes relieve the inflammation about the head of the bone, but will do nothing toward relieving the deformity, and the first attempt at wearing a shoe provokes the whole trouble anew.

Tenotomy is often resorted to as a means of reducing the deformity, but the conditions of the capitulum and the phalanx are often such as to preclude any result from this means, and at best its effect is only imperfect and transitory.

Recourse is often had to amputation, which certainly relieves the abduction of the toe, but is subject to grave objections from the greater deformity inflicted upon the foot, the unprotected position of the remaining toes, and the disturbance to the equilibrium of the body. The diseased head of the metatarsal bone would necessarily be removed, an osseous structure thus be opened, and a risk of greater or less degree to the life of the patient would thus be incurred.

A few years ago, Prof. Hueter, in his "Clinical Treatise on Diseases of the Joints," discussed the disease of which we have been speaking, and stated that the head of the metatarsal bone had been excised for caries with such success as to recommend the operation, and he advises it also in extreme cases of abduction of the toe from other causes, to which condition he gives the name of "*hallux valgus*." The operation, as Hueter performed it, consisted in an incision upon the inner surface of the toe in the direction of its axis, which is carried to some distance on either side of the joint. The capsule is opened, the ligaments are cut, and a subperiosteal dissection of the head of the metatarsal bone is made, the capitulum is removed by bone-forceps or a saw, the toe is brought into a line with the foot, and the wound is left to heal by granulation (Hueter, p. 341 et seq.).

So far as I know, attention was first called to this method of treatment in America, by a paper, describing the operation and accompanied by a report of eleven cases, which was read before the Buffalo meeting of the American Medical Association, by Prof. Frank H. Hamilton, of New York. The cases, with two exceptions, were simply those of deformity either from mechanical causes or from rheumatic or other diseases. Of these eleven cases, six were operated upon by Prof. Hamilton, and all resulted in cure, with the relief of deformity and restoration of the functions of the foot. Five cases were reported from other surgeons with a flattering result in four cases, and one death. The fatal case was that of a gentleman seventy-five years old, who had had extensive disease of the joint with caries and suppuration for three years. Esmarch's bandage was applied and the resection was made with a chain-saw. The foot was enveloped in a warm-water compress. Gangrene of the toe, foot, and leg ensued, and the patient died on the eleventh day. The surgeon who operated in this case ascribes the fatal result to the use of the Esmarch bandage, which is thought to have delayed or even suspended the proper nutrition of the part for a time sufficient to destroy the vitality of the tissues, thus inducing gangrene. That this disastrous result sometimes follows the use of the Esmarch bandage in debilitated subjects, there can be no doubt, and it may easily have been the cause of the fatal result in this case. Prof. Hamilton takes great care to secure the most favorable conditions for the healing of the wound by applying no ligatures or sutures after removing the head of the bone, but by simply immersing the foot in a bath of hot water, where it is kept continuously for a period of from five to seven days, when he says "fomentations may be substituted, or the foot may be taken from the bath at night and wrapped in wet lint covered with oil-silk." This treatment could be more easily carried out in a hospital than in private practice, where the appliances for a continuous bath of a certain temperature are not always easily obtained. Prof. Hamilton adds that "nearly but not quite the same immunity to inflammation and other accidents may be obtained by continuous warm-water fomentations, and without the use of the bath at any period." In any case he advises the use of fomentations for two weeks, when they may be replaced by other suitable dressings. The incision was varied in direction by Prof. Hamilton, so as to form a flap 4½ by 2 cm., thus opening the joint more easily and completely than was the case with the straight incision. The operation was thus rendered easier, and the result was equally favorable.

The cases which I present were of the right and left foot respectively of the same person. The patient, a middle-aged lady, had long been confined to her room, and often to her bed, on account of the pain and disability occasioned by the inflamed state and distorted condition of the heads of the first metatarsal bones. The history was that of a chronic rheumatic arthritis, no doubt aided materially by wearing improperly shaped shoes, though, as is usually the case, the patient denies that the shoes were ever at fault. She was much emaciated from long confinement and suffering, appetite poor, the strength greatly diminished, weight between eighty and ninety pounds. There was a great degree of abduction of both great toes, so that they lay under the bodies of the other toes.

As before stated, there was great pain and almost entire inability to walk; the distal end of the first metatarsal bone was very prominent and knobby, and the articulation between it and the first phalanx was removed from the end of the bone to a point on its outer side. The tissues were stretched over the head of the metatarsal bone; they were red, abraded, and sore. Patient could not wear a shoe, she could scarcely get about the house, and was generally miserable.

Feb. 26th.—Right foot was operated upon by an incision extending 2.5 cm. along the axis of the first metatarsal bone, and connecting with another incision transverse to the course of the bone, thus forming a right-angled flap. This was turned back and the head of the bone exposed. The joint was opened and the head of the bone freed from its attachments to such a degree as to allow a thin steel watchspring saw to be passed behind, when the bone was quickly sawed off at a point about 2 cm. from the distal extremity. There was but little bleeding. The wound was washed in carbolized water, and three silk sutures were applied by which the flap was retained in place. A light carbolized compress and bandage were applied. No ligatures were necessary.

Feb. 28th.—Doing well. No suppuration. All sutures removed to-day. Patient is kept quiet, suffers but little pain, requires no opiate. Appetite good. March 8th.—Eleven days after the operation, wound fully closed. Not much tenderness and no pain. Patient is beginning to walk upon the foot.

March 20th.—Left foot operated upon in the same manner as the right. Wound closed with four sutures. No ligatures were required. The bone was removed a little farther back than in the operation upon the right foot and the wound dressed with carbolized compress and bandage. March 23d.—All sutures removed. No discharge or signs of retained fluid. Pain very slight. No swelling. April 3d.—Fourteen days—wound fully healed. Patient is walking without any pain or discomfort. There are no signs of irritation in the cavity of the joint, and motion of the toe is not accompanied by pain. The patient is much relieved. Can wear a close-fitting boot, which she has not been able to put on for seven years. Goes up and down stairs without difficulty. The appearance of the feet is much improved. The great toe of each foot is brought into proper line and the other toes are resuming their normal shape and position.

In regard to the method of treatment advanced by Prof. Hamilton, it may be proper to notice a few points. He uses no ligatures or sutures, does not make any effort to approximate the edges of the wound, and is quite urgent in his advice that the foot be placed in a bath for some time after the operation, for the purpose of preventing sloughing, etc. He strongly insists that no bandage be used, as being likely to induce gangrene, and his cases are invariably left without trying to unite the lips of the incision, for the reason that such a wound should be left to fill up by granulation. These objections are all, doubtless, well grounded, and in some instances fully applicable, but they would seem to be more or less dependent upon the age and general condition of the individual patient and the condition of his surroundings. They were none of them observed in my cases, and the result was certainly all that could be desired. Union was in both cases entirely by first intention; there was no effusion into the cavity left after removal of the head of the metatarsal bone, and the recovery was very rapid and complete. The only treatment observed other than that mentioned above was rest in bed and a moderate diet.

I do not know why Prof. Hamilton considers it necessary to observe so many details in the performance of this operation and in the subsequent treatment, or rather the subsequent lack of treatment, of the patient. The operation is certainly not more difficult to execute than many other operations upon the extremities, and if the two cases in which I have had opportunity to study it form any indication, the recovery is not subject to more than the average amount of risk and peril. The attempt to follow the explicit directions given by Prof. Hamilton would rob the operation of what, to me, is one of its greatest advantages—its simplicity and consequent ease. To provide the means for constant immersion of an extremity in a bath of a certain temperature, with the observance of other unavoidable conditions, would render the extensive application of this operation outside of large hospitals impossible, and by just so much tend to limit its usefulness; for many, if not most of the sufferers from the disease we are treating, are found in the humbler walks of life. If these inconvenient and costly arrangements can be safely avoided, it certainly is a gain to surgery and to every patient who suffers the operation.

That this may be judiciously advised is proved, I think, by the result of my cases, and I consider that this operation recommends itself in all proper conditions as easy, safe, and satisfactory.

June 16, 1880.—Examination of both feet of this patient to-day shows the great toes in normal line with the foot, not sensitive, with extensive motion, the joints not tender, nor in any way causing her any trouble. The other toes have come into excellent position, and the appearance of the feet is much improved. In fact, both feet are in as good shape and proportion as is found in the majority of so-called healthy feet. Patient is out walking every day, and does a great part of the housework in the family, wearing a close-fitting shoe, and being on her feet several hours each day. Her general health is benefited in almost a similar ratio, and she is loud in her commendation of the operation.

THE ACTION OF THE VISUAL PURPLE IN THE EEL.

By HORATIO R. BIGELOW, M.D.,
WASHINGTON, D. C.

The announcement of Boll of the sensitive purple color of the retina, and its more recent elaboration by Khüne and Ewald, have resulted in many scientific deductions as to the actual part taken by the "purple" in the visual function. The fact that many frogs appear to see perfectly well in "spite of the absence of any store of it in their retinas, and that many animals, which never at any time seem to possess such a store, have nevertheless respectable vision," together with the useful hint thrown out by Dr. Michael Foster, in his excellent translation of Khüne, "On the Photochemistry of the Retina and on the Visual Purple," that "it would be very interesting to ascertain the behaviour when their retinas are bleached, of those animals, if there be any which possess no cones, or rather in which all the terminal organs of the retina are covered with purple," led me to institute some experiments founded upon the general plan of Khüne, as to the action of the visual purple in the eel. The investigation was stripped of some measure of embarrassment, as the idea which naturally suggested itself that frogs, with bleached retinas, though not blind as to the amount and intensity of light, might still be unable to distinguish colors, had already been fully discussed by Khüne, who proved satisfactorily that the presence of visual purple in the rods was not essential to the appreciation of differences of color. Schultze has observed that the retina of the eel contains rods, no cones. Khüne writes: "I have found the retina of both fishes (the loach and the eel) purple; in the loach only faintly so, but in the eel more intensely purple-colored than in any other animal, with the exception of the owl, which in this respect slightly exceeds it. When exposed to light the retinas were often very intensely yellow; to this fact may probably be referred Leydig's statements in reference to the loach; there are, however, differences to be noted. I saw, for instance, in an eel which had died in darkness, the purple pass, when exposed to the light, into a deep orange-yellow which did not bleach for two days, and then did not bleach fully, whereas in another specimen the yellow came out very faintly and disappeared after being exposed for an hour to a dull light. As the retina of an eel, being free from cones, contains no pigment-globules, and the rods, being of a considerable length, are uncommonly rich in purple, a certain agreement with the arrangements in the owl's eye is evident." There seems to be an especial significance in the fact that the store of visual purple is largest in those that inhabit dark places, or whose vision is peculiarly well-defined at night. In the badger, the owl, the eel, and the loach, the quantity is in excess. The deduction from my experiments is not absolute, since it is not improbable that a bleaching process, sufficiently long to ensure success, may interfere with vision itself, and in some cases perhaps destroy it. Two eels which had been kept in thick, muddy water in a dark room for twenty-four hours, and who manifested no want of alacrity in finding the pabulum dropped in for them, were exposed on the second day to a brilliant sunlight from nine in the morning until noon, when they were put back into the tank. They sank to the bottom and exhibited no signs of life for some hours. At five o'clock in the afternoon they were squirming aimlessly about, and only absorbed nourishment as they were brought into immediate contact with it. Particles of prepared food, which previously they had taken with avidity, were passed by, unless appreciated by the sense of touch. Twenty-four hours after the bleaching they were as active as they had been before the experiment, and seemed to recognize the food which had tempted them before. This return of vision I thought due to a redevelopment of the purple from some untouched epithelium. The experiment was repeated on the sixth day with a similar result: when taken from the dark tank and put into one filled with clear water, through which the rays of sunlight were allowed to pass, they again seemed to be guided more by a sense of touch than by sight, although the effect was not as great nor as lasting as when exposed directly to the sunlight.

The eye of one eel, which had been kept in a dark, muddy pool, was then extirpated, and the retina exposed to sunlight, when it immediately passed in a faint yellow which persisted for half an hour, but reappeared in four hours after its enclosure in a dark box. It was then re-exposed to the rays of the sun and was thoroughly bleached in three hours. Again it was shut up in the dark, but the purple failed to reappear. The same result on another eye was obtained with the sodium-light, though the time required was much longer, and the bleaching was not as perfect. I then took two other eels from the dark tank, and placed them in such position that isolated absorption colors of different intensity should fall separately into each eye, using Geissler's tubes and the spectroscope, and in this position kept them for half an hour. Upon examining the retinas I found that a dark blue ray had bleached almost entirely, while the green and the red had exerted but little influence. Although prepared for this result by similar experiments of Khüne, it was and still is difficult to understand its significance. For believing, as I do, that the purple is that part of the visual action which intensifies the power of sight in dark places and at night, I had supposed that the dark blue ray would exert but little if any bleaching power, and I can only account for it upon the assumption of a chemical antagonism, and the rapid absorption of these rays by the purple. In order to procure a good monochromatic light, I made use of common salt in the flame of a Bunsen burner for the yellow; and for the red, ordinary light was transmitted through a glass colored with the suboxide of copper; the blue was obtained by transmitting ordinary light through a glass trough with parallel sides containing an ammoniacal solution of the sulphate of copper, as suggested by Ganot. In using the spectrum, it is important to remember the calorific and chemical changes which it may effect. The action of the phosphorogenic rays of Becquerel upon the visual purple are peculiar, and of great interest in connection with the photochemistry of the retina. An eel which had been placed in the dark tank, so that its eyes should be fixed upon some algæ that were clinging to a rock, was taken out and the eye extirpated as speedily as possible. The retina was dampened and placed upon an iodized silver plate, and exposed to blue light for four minutes, when a faintly reproduced impression of the rock and algæ was seen, which became greatly intensified as the yellow or red ray fell upon it. That the visual purple has the power of fixing the image upon which the dioptric apparatus may rest is now a settled fact, and this image remains for a variable length of time.

DEATH FROM RETENTION OF URINE IN A CASE OF PERI-RECTAL ABSCESS.

By CHARLES B. KELSEY, M.D.,

SURGEON TO THE EAST SIDE INFIRMARY FOR DISEASES OF THE RECTUM, NEW YORK.

The following notes of a case in which I was consulted after the death of the patient, and in which I made the *post-mortem* examination, may be of interest as showing a danger which always attends acute disease in the region of the rectum, and the sad results which may follow a disregard of the ordinary precautions of surgery. The history will speak for itself, and comment on my part is unnecessary.

A gentleman, aged thirty-six years, who had previously been in perfect health, was attacked with an abscess in the right ischio-rectal fossa. After a week of suffering it was opened and a large quantity of pus evacuated, and at the time of his death, which occurred suddenly about a week after the incision, it was gradually closing up. From the first of his attack he had complained daily of pain in the region of the bladder. He passed urine very frequently and in small quantities, and only once obtained any relief, which was when his nurse, on her own responsibility, put hot compresses over the abdomen. As a result of this application, he passed a very large quantity of urine, and for a few hours was free from suffering. For the relief of this pain opium was prescribed and freely administered up to the hour of his death. A few hours before the end he expressed himself as feeling very well and hopeful, expected to be about his business again in a few days, and complained only of constant pain over the bladder, and desire to urinate, wondering why he was obliged to pass his water so frequently, and why it only came away in such small quantities. He died, without warning, in a convulsion.

The *post-mortem* examination was made by myself, at the request of the family, who were not quite satfied with the diagnosis of apoplexy which was made by the physician in attendance.

The cerebral sinuses were very full of blood, veins of the dura mater distended with black blood, and the ventricles filled with serum. The bladder reached to the umbilicus, and must have been nearly at the point of rupture. The kidneys were slightly enlarged and gorged with blood, but not otherwise diseased. With these exceptions and that of the abscess which I have mentioned, the viscera were as healthy as I have ever seen them at an autopsy.

A CASE OF MIXED ASTIGMATISM,

Supposed to have been Caused by the Sucking of the Eye by an Infant.

By DAVID WEBSTER, M.D.,

NEW YORK.

On May 20, 1873, Dr. C. R. Agnew was consulted by a lady thirty-six years of age, on account of impairment of vision of her right eye. The commencement of her trouble dated back about eight years, when she first noticed a straight black line running obliquely across the right visual field. This line soon became crooked, and was broken up into numerous transparent specks. These floating, transparent globules eventually mostly disappeared, and the eye, after many months, settled down into a condition in which all objects seemed "distorted" and everything was "double lined." "The gas-flame," she observed, "had a halo with radii about it." She has not now, nor has she ever had, any external appearances of inflammation or irritation.

At the time the trouble was ushered in the lady was weaning her babe, and, curiously enough, fell into the habit of allowing the little one to suck her right eye as a substitute for her nipple. She positively affirmed that almost every night for six months she allowed the child to go to sleep resting on her right arm, and with his mouth applied to her right eye. This gave her no pain, and she indulged the child in it, not thinking it would do her any harm. She now believes that the trouble in her eye was induced by the long continued and often repeated suction exerted upon the eyeball by the mouth of her child. Examination with the ophthalmoscope reveals nothing abnormal except astigmatism. Without a glass the vision is $\frac{8}{100}$, but is raised to $\frac{20}{20}$ with $-\frac{1}{10}$ c. axis 70° $\frown$ $+\frac{1}{42}$ c. axis 160°. The fellow eye has vision $\frac{20}{20}$, and is emmetropic.

Whether the frequently repeated and long continued suction applied to the eye had anything to do with the change in its shape is a difficult problem to solve. For my own part, I am inclined to think that it did. It is certain that the astigmatism was developed during the period in which the eye was habitually subjected to suction. It may be objected that the traction would affect only the loose and yielding eyelids. It seems to me probable, however, that the lips of the child would often make more or less pressure upon the eyeball anterior to its equatorial region. This seems to be borne out by the history of the case, for there seems to have been a slight hemorrhage into the vitreous, probably caused by intermittent pressure upon the globe.

Veratrum Viride as an Antidote to Opium Inebriety.—Dr. J. S. Haldeman claims that as veratrum viride is a direct antidote to acute opium-poisoning, it will also act antagonistically in chronic opium-poisoning. Some cases illustrative of this are referred to.—*Lancet and Clinic.*

Reports of Hospitals.

THE PHILADELPHIA HOSPITALS.

Notes of Practice and Peculiarities of Treatment.

SACCHARINE DIABETES.

In the hygienic treatment of this disease at the University Hospital, Dr. Pepper's first effort is directed toward cutting off the supply of all the starchy elements of food. If the urine becomes less abundant under this exclusive regimen, some hope of ultimate cure is held out. In some very obstinate cases, even after excluding all starchy matter from the diet, the urine still continues to contain a large proportion of sugar.

The best diet for a diabetic patient, in Dr. Pepper's opinion, is, for breakfast, eggs and any kind of meat except oysters, gluten bread and tea, or coffee, with milk and without sugar; for dinner, tomatoes, lettuce, onions, spinach, string-beans, meat, light sour wine, and lemons, or perhaps oranges, but none of the sweet fruits; for supper, about the same diet as for breakfast. None of the starchy foods, no alcohol and no sugar are allowed.

Among drugs opium is regarded as the most valuable; of this an immense amount has been taken daily in several instances without producing any of the symptoms of poisoning. A boy lately under treatment for this disease took seven grains of opium per diem. In his case the only bad effect was the production of obstinate constipation. Cases have occurred where even this was unnoticed. The opium, either directly, by diminishing the amount of the secretions, or, more probably, by its action on the nerve-centres, relieves the excessive thirst and voracious appetite, and reduces the amount of urine and the quantity of sugar in the urine. In one case the amount of urine secreted daily was reduced from twenty-eight pints to eleven pints, and the total amount of sugar in the urine decreased in proportion. Ergot, which has been found to act almost like a specific in simple diuresis, has also been employed in saccharine diabetes with much profit. The dose commonly given is one fluid drachm of the fluid extract four times a day. Where the skin is rough and dry, jaborandi has been shown to be of value by reason of its great powers of diaphoresis. When jaborandi is employed, the opium and ergot are discontinued.

HYPODERMICS OF ERGOTINE FOR FIBROID TUMORS.

The results of the hypodermic injections of ergotine in cases of submucous fibroid tumors of the womb have been very good in Dr. Goodell's wards of the University Hospital. The womb contracts under the influence of the ergot and forces the tumor into the uterine cavity, thus converting it into a polypus. The habit is to inject daily ten minims of a solution containing ninety grains of ergotine to the fluid ounce of distilled water, under the skin of the patient's abdomen.

Three different results have followed this use of ergot in such cases: 1. The fibroid has been simply diminished in size. 2. The fibroid has been converted into a polypus, by being forced into the cavity of the womb, whence it has been removed by forceps; or, 3. Necrosis has followed. This necrosis has been brought about by the diminution in the blood-supply following the contraction of the womb substance; as a result of this, the tumor first atrophies, and then breaks down in the direction of the least resistance.

ENDARTERITIS.

Dr. Bartholow has great confidence in the value of small doses of opium as a cardiac and nervous sedative. His patients in the Jefferson Medical College Hospital, receive five drops of the deodorized tincture of opium every four hours. To arrest the usually accompanying condition of chronic arteritis, the hypophosphites, cod-liver oil, and quinia are employed. One fluid drachm of the lactophosphate of lime and three minims of Fowler's solution are given thrice daily, in addition to the opium. When any improvement is visible in the condition of the patient, quinia is given in energetic doses. It has been shown to have a good effect upon the coats of the arterioles.

MULTIPLE SCLEROSIS.

According to the same authority, the therapeutic indications in these cases are the carbonate and the iodide of potassium. Five grains of each of these salts are ordered three times a day, before meals. From half a fluid drachm all the way to one fluid drachm of the syrup of the iodide of iron is given after meals.

ASTHMA.

Dr. Bartholow has succeeded in affording great relief to sufferers from this distressing complaint by the administration of fifteen grains of the iodide of potassium and twenty grains of the bromide of potassium four times a day. This combination has been found to be particularly useful where there is any spasm of the bronchi.

SCLEROSIS OF THE LIVER.

The watery purgatives—the so-called hydragogue cathartics—are the chief means employed of getting rid of the ascites. Dr. Bartholow orders from one to two drachms of the compound jalap powder every morning. With a view of acting upon the liver, and stopping the sclerosis he orders the one-twentieth of a grain of the chloride of gold and of sodium thrice daily in pill form. Chloride of gold acts on the hepatic cells and retards the hyperplasia of connective tissue.

SCIATICA.

In a case of chronic malaria, with chills and fever, followed by neuralgia, Dr. William Pepper's treatment consists in the use of quinia, iron, arsenic, and belladonna. In many cases, he has found that more relief is afforded by large doses of arsenic than by any other remedy. Occasionally he has injected the arsenic under the skin. When there is distinct local inflammation, he is accustomed to treat the case with large doses of the iodide of potassium and with minute doses of the bichloride of mercury. When he desires to bring about absorption of the inflammatory matters inside the sheath, he has found the best treatment to consist in severe blistering, or in the use of the actual cautery.

The actual cautery, in particular, has been shown to possess great absorbent power, and powerfully relieves over-sensibility of the nerves. Another excellent plan of treatment sometimes pursued consists in the hypodermic injections of morphia and atropia right down into the adjacent muscular structure. For this purpose the habit is to employ from the one-sixth to the one-fourth of a grain of morphia, and from the one-ninetieth to the one-sixtieth of a grain of atropia. As the disease subsides, care is taken that the morphia-habit is broken up. In still other cases, where the localized pain has been intense, the most satisfactory results have been derived from the hypodermic injection of from eight to ten minims of chloroform into the adjacent tissues, great care being had to keep the needle out of the way of the arteries. Though incomparable as a temporary destroyer of pain, the effects of the chloroform are not permanent. Galvanism has been employed with success in some cases. The mode of application is with the positive pole at the seat of pain, and the negative pole along the nerve-trunk. Where the muscles have wasted to any great extent, the faradic current is the one which is generally the best to employ.

CHRONIC DIARRHŒA AND PERITONITIS.

The routine treatment of this condition, in Dr. Da Costa's wards in the Pennsylvania Hospital, has consisted in the use of a strict milk diet, together with from the one-fourth to the one-third of a grain of the nitrate of silver, administered every two hours in pill form. At the same time iodine ointment is applied to the patient's abdomen, twice daily. Lately, however, Dr. Da Costa has adopted a new plan of treatment, which has greatly improved his patients' conditions. This treatment has consisted in the injection of five minims of Magendie's solution of morphia into the abdominal walls every morning and evening. This method of treatment has given great relief to the patients. It was first tried a number of years ago in some very obstinate cases of chronic diarrhœa, with very good results, better results than Dr. Da Costa has ever been able to obtain from the hypodermic injection of morphia into other parts of the body.

CHRONIC HYPERTROPHY OF THE TONSILS.

Dr. Penrose's treatment of these cases is both general and local. He regards the general or constitutional treatment as very important, particularly as such patients are generally cachectic. Unless this general treatment is rigorously carried out, the local treatment is of no avail. The first thing to be done is to remove any bad hygienic surroundings which may exist. He then begins with mercurial purgatives and revulsives. He gives from the one-twelfth to the one-half of a grain of calomel every two hours, in a little sugar, until the child has from three to six movements every day. This calomel treatment is continued every two or three days for several weeks. At the same time, as a stimulant to the system, the child's whole body is thoroughly rubbed with hot whiskey before going to bed. If the patient is decidedly weak, one fluid-drachm of brandy, well diluted, is given internally from three to six times daily. Patients have been kept upon these daily rations of stimulus for weeks at a time. Rubbing the body with hot whiskey has been followed by the most excellent results. The other items of the constitutional treatment consist in the use of from three to six grains of quinia daily, and from five to ten drops of the tincture of the chloride of iron, from three to four times daily, in water. At the same time, the child is fed up well with plenty of good soup, milk, eggs, and extract of malt. The object is to rebuild the whole fabric of the body, at the same time that all the diseased products are being removed in the alvine evacuations.

The local treatment is regarded as very important, but the local treatment is of no avail unless the constitution is regenerated by means of the remedies already indicated.

If the inflammation and hypertrophy are considerable, Dr. Penrose is in the habit of applying a solution of the nitrate of silver (sixty grains to the fluid ounce of distilled water) to the parts, by means of a brush. The application is made carefully and thoroughly. A small brush is used, and care is taken not to catch up too much of the astringent solution on the brush. The effort is made to secure the child's co-operation, and great care is taken that the brush is properly secured to its handle.

Powdered alum has been found to be another very excellent application in these cases. The following formula is ordered:

℞. Pulv. alum........................ ʒ ij.
Sacchar........................ q. s.
M. et in chart. No. xx. div.
Sig.—One powder every two hours.

The child is taught to take a pinch of the powder every now and then, and not to swallow the whole thing at once—this with a view of prolonging the contact of the medicine with the diseased tonsils. When the child is large enough, lozenges of the chlorate of potassium are often very efficient.

Another mild but excellent local application is the tincture of the chloride of iron with glycerine—one fluid ounce of each being applied by brush, once or twice a day. But very few cases resist this combined treatment. The constitutional treatment is kept up until the tonsils have been reduced to their proper size.

If the child is pigeon-breasted, a great deal has been accomplished by careful gymnastic training. Dr. Penrose is very much in the habit of recommending the use of three-wheeled velocipedes for the purpose of developing the chest, or, as a systematic item of treatment, he has the child stand with its back against a wall, tells it to take a full breath, and then, when its lungs are thoroughly expanded, institutes firm pressure against the sternum.

AMENORRHŒA.

In cases of this nature, due to torpid action of the ovaries, Dr. Goodell orders the following prescription:

℞. Ex. aloës.................. ℈ j.
Ferri sulph. exsic.................. ʒ ij.
Assafœt.................. ʒ iv.
M. et in pil. No. C. divide.
Sig.—One pill to be taken after each meal. This number to be gradually increased, first to two and then to three pills after each meal.

If the bowels are at any time over-affected, the patient is to stop and begin again with one pill.

Where the amenorrhœa is due to arrested development, Dr. Goodell has derived the very best results from the constant use of Blot's pill, as recommended by Niemeyer:

℞. Pulv. ferri sulph.,
Potas. carb. puræ................āā ʒ ij.
Mucil. tragacanth................ q. s.
M. et in pil. No. xlviii. div.
Sig.—To be given daily, in increasing doses, until three pills are taken after each meal.

This gives the large quantity of twenty-two and a half grains of the dried sulphate of iron per diem.

If these pills give rise to constipation, Dr. Goodell uses this formula:

℞. Pulv. glycyrrh. rad.,
Pulv. sennæ..................āā ℥ ss.
Sulphur sublim.,
Pulv. feniculi..................āā ʒ ij.
Sacchar. purif.................. ℥ jss.
M. Sig.—One teaspoonful in half a cupful of water at bedtime.

Where the suppression is due to change of habits and loss of health, tonics are employed. When the suppression comes on suddenly, from cold or exposure while in the midst of the menses, and is accompanied by severe lumbar pains, the patient is placed in a mustard hip-bath, a Dover's powder is administered, she is put to bed and hot drinks are given to provoke copious diuresis and diaphoresis.

TUBERCULAR LARYNGITIS.

Dr. William Pepper's general treatment of such cases is the same as that for phthisis. Locally he applies pure nitric acid, or strong solutions of nitrate of silver are brought into contact with the ulcers. Extreme care is had in making these strong applications, and a delicate brush holding the caustic is guided carefully to its destination, by the aid of the laryngoscope. For the œdema astringent solutions, such as the sulphate of zinc, copper, or alum are recommended. Gargles and inhalations are used for the cough.

The following formula has been found to be of particular value:

℞. Tr. benzöici comp............. f. ʒ ij.
Glycerinæ.................... f. ℥ ss.
Aquæ........................ f. ℥ iv.
Sig.—To be used as a gargle.

Inhalations of steam vapor of hops, or conium, are very often found useful as palliatives. In many cases counter-irritation is applied externally to the larynx in the shape of small blisters. To relieve the sense of fulness lozenges or hæmatoxylon, krameria, or tannic acid are prescribed. In desperate cases tracheotomy is performed, and a metal tube worn, thus putting the much-worn larynx to rest.

ADDISON'S DISEASE.

Rest is the chief indication, according to the same authority, with good hygienic influences and wholesome food. In some cases an exclusive milk diet has been found to do great good. The bowels and other excretions are carefully attended to. No long journeys are allowed. The system is sustained upon arsenic, iron, and cod-liver oil. Counter-irritation over the seat of disease has been found useful in early stages, so also with regard to faradization with mild currents or general principles, nitrate of silver and iodide of potassium are administered. The former drug has shown itself to be of great use where there is irritability of the stomach and intestines present. Where the vomiting is violent and otherwise uncontrollable, chlorodyne or temporary enemata are used. Where there is palpitation and dyspnœa, digitalis is given freely.

The following prescription, originally recommended by Greenhow, has been employed very satisfactorily in a number of cases:

℞. Ferri sesquichloridi,
Chloroformi.......... ....āā ♏xv.—xx.
Glycerinæ.................. f. ʒ ij.
M.
Sig.—To be given three times a day in water.

The form of iron which Dr. Pepper has lately employed in this affection is dialyzed iron. He does not place much confidence in phosphorus, which was formerly much used in Addison's disease. Alcohol is given in small quantities and in whatever form is best assimilated by the stomach. Strychnia seems to do good in some cases.

Progress of Medical Science.

Elementary Tubercles and Giant-Cells.—Some time ago, M. Kiener communicated a paper on this subject to the *Société de biologie* of Paris. At a recent meeting of the same society, Malassez commented on this paper, corroborating some points of Kiener and disputing others. The following is a brief résumé of his observations: The simplest tubercles are utterly devoid of giant-cells, being composed solely of lymphoid or embryonal corpuscles. Tubercles with epithelioid bodies and giant-cells are not of this simple kind, and should not, therefore, be regarded as belonging to the elementary form of tuberculosis. True giant-cells represent neither cross-sections of obliterated vessels, nor are they accumulations of degenerated elements. They are cellular bodies of perfect vitality, but as yet incompletely developed, probably corresponding to fragments of the vaso-formative networks of Kiener. These reticula were discovered by Kiener in the tubercles of serous membranes, and are not destined to be transformed into capillary blood-vessels. Arrest of development in these capillary new growths, together with structural alterations in the pre-existing vessels, explains the tendency toward degeneration of tubercular tissues. Such tissues receive less blood on account of the obstructed vascularization, and in addition, the blood-supply may fail of ultimate distribution, owing to the arrested development of the new formed capillaries.—*Gaz. méd. de Paris*, April 10, 1880.

A Case of Spina Bifida.—An interesting case of this rare affection is reported by Dr. J. E. Blake, of this city. The patient, a female, aged eight years, has spina bifida in the lumbar region. At the time of birth the sac was about the size of a pigeon's egg, having an opening leading into the vertebral column, about the size of the nail of the forefinger. The sac is covered by a lipoma of which the bulk of the tumor is composed. A striking feature of the case, and which could be demonstrated until the fontanelle closed up, was the existence of a free communication between the sac and cranium; this was shown by exerting pressure on the sac when a bulging up of the fontanelle occurred. At first there was difficulty in retaining the urine, owing to weakness of the sphincter vesicæ, but this was to a certain extent overcome by efforts of the will. There is an arrest of development of the bones in the vicinity of the ankle. The muscles of the anterior aspect of the leg are paralyzed, and there is a lack of development of them; the circulation of this part is somewhat enfeebled. The posterior muscles of the lower extremities are fully developed, as is the upper portion of the body. With these exceptions the child is in perfect health, but, on account of the paralysis of the legs, is compelled to go about in a wheel-chair. To protect the sac from injuries of any kind, pressure was brought to bear on it by means of elastic webbing applied in such a manner as to cause fulness of the fontanelles.—*Reprint from Am. Journ. of Obstet.*, April, 1880.

* * *

Citrate of Caffein is gaining favor as a diuretic. In several cases of cardiac dropsy in which the remedy was tried by Assistant Surgeon W. H. Heath, at the New York Marine Hospital, the increased flow of urine was very marked and rapid.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, July 10, 1880.

WHETHER VIVISECTION PAYS.

In the July number of *Scribner's Monthly* is an article by Mr. Albert Leffingwell entitled, "Does Vivisection Pay?" The writer takes the ground that it does not pay, at least not very well, and he argues the point with an apparent candor and moderation which must make his article very effective with readers not especially informed upon the subject in question. The great importance—the vital necessity, indeed—of vivisection to the progress of scientific and practical medicine, needs no demonstration to physicians. There are, however, many of the laity who, without knowing much regarding the facts, have yet a good deal of sympathy with the appeals to their humanity made by anti-vivisectionists. For this reason we venture to comment upon some of the points made by Mr. Leffingwell, in the article to which we have referred.

The writer freely admits the necessity of vivisection. He asserts, however, that it should not be performed for the purpose of class demonstration, when the point to be demonstrated involves pain to the animal and is one already well established. He also claims that, to use his own words, "in view of the slight gain to practical medicine resulting from innumerable past experiments of this kind, a painful experiment upon a living vertebrate animal should be performed, by law, solely for purposes of original investigation, and then only under the most rigid surveillance, and preceded by the strictest precautions." These precautions are the obtaining special permission from a State board, the applicant being obliged to state the object of the proposed investigation, the nature and method of the operation, the kind of animal to be experimented on, and the shortest period during which pain will probably be felt. An officer of the State must also be given an opportunity to be present during the experiments. Mr. Leffingwell further insists that those purely physiological experiments should not be permitted, which, though not painful in themselves, lead to mutilation and subsequent suffering in the animal.

These are the main points which are advocated. But, in leading up to them, there are a number of statements made which, if not entirely false, are very misleading.

We are informed, for instance, that the more brutal methods of physiological experiment, so current on the continent of Europe, are those followed in our New York schools; and again, that the results of vivisection upon practical medicine have been really almost nothing. As evidence of the first assertion, a number of experiments, annually performed in the medical colleges of this city, are described. The fact that these experiments are all done under anæsthetics is not brought out at all, and the average reader would gather that our physiological professors are hardened creatures who annually brutalize their pupils by unnecessary demonstrations of well-established laws. These charges, we believe, from all the evidence we can gather, are neither more nor less than silly exaggerations. There is no place in the State or country where more physiological experimentation is done than at the College of Physicians and Surgeons, of New York. In all the class demonstrations annually made at that place, however, there is but one experiment in which there is any exhibition of the infliction of pain. This is one in which the animal is made to utter cries for a short time in order to show the motions of the vocal chords in speech. The idea that there is anything brutalizing in the physiological lecture course will certainly appear novel to the medical student, and is absurd to every one who knows anything about the facts.

Class demonstrations of known physiological laws are almost, without exception, painless. They are of the greatest possible help in impressing facts and in elucidating clearly what is obscure in the human mechanism. The history of the development of physiological teaching at Harvard illustrates this. The introduction of physiological experiment revolutionized the study at that college, and turned a dull routine into enthusiastic application.

In regard to the other kind of experiments—those conducted in the interests of physiological science alone—the impression conveyed by Mr. Leffingwell is equally unfair. Among the many experiments performed during the past few years at the laboratory in Twenty-third Street, there has been only one set that has been attended with pain. This is the series undertaken for the purpose of locating the cerebral functions, especially those of the cortex. Here some pain, though not a great deal, had to be inflicted. But the scientific results attained are more than commensurate with the suffering that was caused. The brute must regularly suffer that man may eat and enjoy himself. Society acknowledges this. He must also suffer occasionally that man may increase his knowledge. But that unnecessary suffering is inflicted, that anæsthetics are not given whenever possible, is untrue.

Upon the question of the practical results of vivisection, our writer is particularly emphatic, and, we may add, particularly narrow and ignorant. He did once, he says, believe that vivisection had contributed much to practical medicine. But he has seen a new light, and now he knows he was mistaken. To support this view, that practical medicine has not been advanced, he quotes a number of opinions of eminent men. The quotations are short and are some of them from documents nearly ten years old. Furthermore they are not to the point, for this is a question of facts, not opinions. We are aware that a great deal of reproach still hangs around physiological therapeutics. It has, they say, found us no specifics, it has not furnished us with any of our most reliable drugs, but has given us only a mass of questionable theories. This is in a measure true. Physiological laws must be practically applied with great caution in administering drugs, and the physiological therapeutist must be a man of great good sense or he will be unsafe. For all that, we believe it impossible to place too high a value on the physiological method in therapeutics. No stronger argument, in the first place, for this view can be given than by contrasting the old text-books on therapeutics with those of Wood and Bartholow. The study of materia medica and therapeutics was formerly a mechanical routine, which exercised only the memory. Now it is one of the most interesting branches of medical science. It claims at once the attention of the student, it calls into exercise his best reasoning powers and introduces him to the most recondite phases of physiological law.

As for the direct practical results, it should be remembered first, that empiricism is four thousand years old, and physiological therapeutics hardly more than thirty. With this in mind, no sane man would condemn the possibilities of the latter, from what it has already done. It has certainly produced results large enough to justify our encouraging further work in every way.

We have not space to go into many particulars. We would recall the fact, however, that, by vivisection, Galen discovered that the arteries contained blood, Harvey discovered the circulation, and Aselli the lacteals. In later times Hunter discovered, by the same method, the use of the ligature for his treatment of aneurism, and the laws of collateral circulation. The use of the narrow ligature came also from experiments on living animals. By the same means, our knowledge of fractures and their mode of healing has been practically enlarged. Sédillot justified and introduced gastrotomy by his vivisections; nephrectomy was introduced in the same way. Ollier and Heine showed through it the periosteal reproduction of bone. Vivisection has given most valuable and practical information upon the healing of wounds of all kinds. The transfusion of blood is due to vivisection entirely. We have learned from it the mechanism of the heart-sounds, normal and pathological. Before the time of Fothergill, digitalis was used but slightly and hesitatingly. The knowledge of its physiological action which he gave us has greatly extended and defined its usefulness. Half a century ago, gelatine was a very popular article of diet, especially in France. It was thought to be extremely nutritious; one pound of it was alleged to be equal to six pounds of meat. The investigations of Magendie and the French Commission showed the falsity and danger of these ideas about the food. The experiments made to determine the functions of the liver and glands of the intestinal tracts have furnished data that are of immense practical value. Witness the extended use of pepsin and pancreatin. Rutherford's experiments have given us a new cholagogue and throw much light upon the action of old ones. Without Liebreich's vivisections, we might never have had chloral. Nitrate of amyl comes to us through the same channel; so do many of the uses to which we now put atropia. The antagonism of medicines, as of strychnia to chloral, of atropia to physostigma and opium could never have been definitely known without practical experimentation. Finally, there have been few contributions to practical medicine which have a higher value than those upon the nature of fever. The experiments of Burdon Sanderson and others, which showed that many of the symptoms in the various fevers were due to the heat, and were not a necessary expression of the specific poison in the system, would go far of themselves to negative the charge of the inutility of vivisection.

We have quoted enough, therefore, and believe it has been shown that the past usefulness and future promise of vivisection cannot be ignored or belittled. Vivisection is a real necessity to science, and it should not be hampered by any close legal restrictions. Our physiologists are not brutes, who need constant watching to curb their inhumanity. The amount of suffering that takes place in the physiological laboratories of this city is immeasurably less than that inflicted every day in our streets by impatient drivers and mischievous boys. We hope therefore, that these laboratories will be let alone. There is little enough scientific research in this country without putting checks on what already exists.

CARDIAC HYPERTROPHY IN RELATION TO RENAL DISEASE.

In a recent issue we alluded to the pathology of granular kidney, and this naturally suggests the present subject. Hypertrophy of the heart and renal disease, especially granular kidney, are frequently found to be associated. The fact has long since been recognized that this was no accidental coincidence. But precisely what was the nature of the interrelations between these pathological states has never been satisfactorily shown, so that in place of accurate knowledge we have only a multitude of various theories in explanation of the matter. Dr. Robert Saundby (reprint from the *Birmingham Med. Review*, January, 1880), by combining and comparing pathological, clinical, and experimental data, has reached several conclusions, which seem to deserve some attention in this connection. He finds that "in chronic Bright's disease the augmentation of the cardiac function is compensatory to the renal defect,"—a view which in his opinion "confirms the propriety of the practice of administering digitalis in these cases." But he adds that, "as far as possible, elimination should be favored by the skin and bowels, while the diet should consist of elements containing as small an amount of urea-forming substances as the general condition of the patient may warrant." It is further stated that "the high tension pulse indicates a high degree of toxæmia and relative failure of the kidneys." Blood impurities, he believes, are early and important phenomena in granular kidney. This we may at once assent to, since it is well known that urea and various extractive matters of the blood, are largely present in this fluid after the inhibition of the secretory activity of but a single kidney. Witness the cases of nephrectomy. The interesting experiments of Growitz and Israel (*Virchow's Archiv*, vol. lxxvii., p. 315) are also adduced by the author in support of this view. These writers, it will be remembered, found that unilateral artificial nephritis, or the removal of one kidney, was invariably followed by cardiac hypertrophy, and they also concluded, from accurate measurements, that this hypertrophy was actually compensatory for the renal defect, inasmuch as it bore a definite proportion to the amount of renal substance eliminated.

Moreover, Bright (*Guy's Hosp. Rep.*, vol. i., p. 397) had already intimated some such hæmic origin of the enlarged heart, for he distinctly says: "This naturally leads us to look for some less local cause for the unusual efforts to which the heart has been impelled; and the two most ready solutions appear to be either that the altered quality of the blood affords irregular and unwonted stimulus to the organ immediately, or it so affects the minute and capillary circulation as to render greater action necessary to force the blood through the distant subdivisions of the vascular system." Thus, it seems that after many years of observation and experimental investigation with the aid of all our modern improved methods, we are once more reverting to the explanations given by Bright over forty years ago.

According to Dr. Saundby, then, we are to regard the cardiac hypertrophy as "directly dependent on the state of the blood," and hence the characteristic rise in blood-pressure associated with Bright's disease, must be interpreted as its effect instead of as its cause. An increase in the capillary resistance, combined with the increased vigor of the heart's action, will therefore be the determining factors of the peculiar pulse observable in Bright's disease. But, "as the toxic material in the blood stimulates the heart and probably the kidneys, without raising the blood-pressure," we may observe increased secretion of urine or albuminuria before there is any perceptible modification of the patient's pulse.

These somewhat theoretical considerations are not entirely devoid of practical bearings, if only to teach us again the great importance of repeated and careful examinations of the urine. For it is only in this way than we can hope to diagnosticate the condition of granular kidney in its incipiency, and thus institute an effectual, because early treatment.

Reviews and Notices of Books.

THE ART OF PERFUMERY AND THE METHODS OF OBTAINING THE ODORS OF PLANTS: The Growth and General Flower Farm System of raising Fragrant Herbs, with Instructions for the Manufacture of Perfumes for the Handkerchief, Scented Powders, Odorous Vinegars, and Salts, Snuff, Dentrifices, Cosmetics, Perfumed Soap, etc. By G. W. SEPTIMUS PIESSE, Ph.D., F.C.S., Analytical Chemist, Author of "Chemical, Natural, and Physical Magic," "The Laboratory of Chemical Wonders," etc. Fourth Edition. Philadelphia: Presley Blakiston, 1012 Walnut Street. 1880.

MR. PIESSE's work on perfumery is in the fullest sense comprehensive. It treats of the subject from a technical as well as from a scientific standpoint.

After considering the history and properties of odors, it passes on to the philosophy of them, and, under the head of "Gamut of Odors," says: "Scents, like sounds, appear to influence the olfactory nerve in certain definite degrees. There is, as it were, an octave of odors like an octave of music; certain odors coincide, like the keys of an instrument."

"The analogy is completed by what we are pleased to call semi-odors." "If a perfumer desires to make a bouquet from primitive odors, he must take such as chord together."

"The perfume will then be harmonious."

After describing the different methods of extracting the odorous principles, as enfleurage, distillation, etc., there follows an exhaustive article on each of the agents which go to make up the perfumer's armamentarium. A full list of forms for perfumes and toilet preparations is given.

The portions of the work most important to the physician are those devoted to medicated soaps. The manner of combining such remedial agents as *sulphur*, *iodine*, *mercury*, etc., is described, and the important point noted that the absorbent vessels of the skin are very active during the lavatory process. It may be here stated that a medicated soap may be made, either by adding the agent to the melted soap, or beating it up with soap-curd and by expression forming it into the conventional cake.

Under the head of preparations for the hair, dyes, washes, and depilatories are considered. Two forms for the latter are given:

Slaked lime	3 parts.
Orpiment	½ part.

Quicklime	10 parts.
Sulphuret of sodium	3 "
Starch	10 "

The chemical portion of the work is important, and, in an appendix, methods are given for detecting adulterations in the different perfumes, and for the preparation of artificial fruit-essences.

There is also an article on the application of organic chemistry to perfumery.

Rocky Mountain Health Resorts: An Analytical Study of High Altitudes in Relation to the Arrest of Chronic Pulmonary Disease. By Charles Denison, A.M., M.D., etc., etc. Boston: Houghton, Osgood & Co. Riverside Press, Cambridge. 1880.

Doctor Denison, who has devoted much study to climatic influences in pulmonary disease, has presented us with a very readable, exhaustive treatise, as may be inferred from the title. It abounds in information of a character which is incapable of being reproduced in a review, and we therefore content ourselves with recommending it as a conscientious contribution to the literature of the subject. Even as a guide-book its value cannot be too highly estimated. A chest-examination chart, contained in a pocket-cover of the book, is intended to stimulate thoroughness in observations and a greater attention to important details.

Pathogenetic Outlines of Homœopathic Drugs. By Dr. Med. Carl Heinigke, of Leipzig. Translated from the German by Emil Sietze, M.D., of Philadelphia. New York and Philadelphia: Boericke & Tafel. 1880.

The author of this book has sought to fill an existing hiatus in the literature of homœopathic materia medica by producing a work without the bulky repertories of the text-books of Drs. Noak, Trinks, Clotar Mueller, and Jahr, authors who published about thirty years ago. He considers that the topical registration of pathogenetic symptoms renders difficult the understanding and easy survey of the drug-provings, and he therefore has in the present work arranged the registration of symptoms according to the *anatomico-physiological schema*. Dr. Heinigke states that the repertory to be added is merely to serve the purpose of presenting to the reader a group of remedies standing in specific correlation to certain organs and tissue-symptoms, and to direct the attention to the comparison of the characteristic pathogenetic features of a definite category of drugs, without, however, giving rise to the impression that their special study would thus be rendered superfluous.

In the author's introduction he claims that "the consideration and practical adaptation of the discovery that certain substances—which, as unprepared (crude, matter, are unable to produce a medicinal effect of any kind upon the organism—in a homœopathically prepared state, affect certain organs and tissues of the body in a definite manner, so that truly 'specific effects' must be ascribed to them, have remained to this day the exclusive property of the homœopathic school." However correct this assertion may be when applied to the German profession, it certainly has no application here, where it is not unusual to find upon a physician's shelves the works of Hughes and other writers alongside those of Ringer, Phillips, and Bartholow, while his medicine-chest contains many of the favorite remedies of the so-called homœopathic school. Whatever the judgment of individual members of the profession may be as regards the value of the drugs above alluded to, or of other preparations whose actions are homœopathic, as aconite and pulsatilla in small doses for neuralgia, or ipecacuanha for vomiting, certain it is that the number who find it profitable to investigate remedies of all kinds, when of imputed value, is steadily increasing.

A more special study of drugs can but still further relieve the homœopathic materia medica of inexact and verbose literature; and when provings are made to a greater extent than now by well-trained observers, the pathogenetic outlines of drugs will be apt to attract the attention of a greater number of educated medical men than heretofore.

The Student's Manual of Venereal Diseases; being the University Lectures delivered at Charity Hospital, B. I., during the Winter Session of 1879–80. By F. R. Sturgis, M.D., Clinical Lecturer on Venereal Diseases in the Medical Department of the University of the City of New York, etc., etc. New York: G. P. Putnam's Sons. 1880.

An unpretending volume of no little merit, in which italics, by way of emphasizing facts and propositions, are used with a rare judgment. The scope of the work is elementary, its style concise, and, as the author states in his preface, its aim practical. We bespeak for this little venture a well-deserved success—at all events, we are assured that there will not be imposed upon the purchaser much useless reading.

The Watering-Places and Mineral Springs of Germany, Austria, and Switzerland; with Notes on Climatic Resorts and Consumption, Sanitariums, Peat-, Mud-, and Sand-Baths, Whey- and Grape-Cures, etc. A Popular Medical Guide. By Edward Gutmann, M.D. With illustrations, compartive tables, and a colored map, etc. New York: D. Appleton & Co. 1880.

A medical Baedeker, quite complete, red cover and all. A novelty to be seen, not without some of the defects incidental to such new books by new authors, but a very welcome novelty nevertheless. This work of 331 pages, we are told, is not intended to be a "learned discourse on the physiological effects or chemical compositions of the springs, but a popular medical guide," for the purpose of making Americans, "unacquainted with the continental mode of living," somewhat "familiar with the arrangements, manners, and customs of living at the principal watering-places of Central Europe."

Dr. Gutmann has certainly performed a creditable task, and although his little book is not, strictly speaking, a medical essay, still the practitioner will not fail to find useful information scattered through its pages. For the annually increasing exodus to Europe will doubtless include some of his patients, and quite likely these have questioned him concerning the choice of their summer residence. All such questions he will be better prepared to answer after having glanced over Dr. Gutmann's book, and so far it forms a desirable acquisition to the physician's library.

It is evident at once, from the author's familiarity with all the details characteristic of the modus vivendi at the various places described, that he has himself repeatedly visited them. In fact, he tells us in his preface that he has "for the last ten years frequented all the important watering-places of Germany, Austria, and Switzerland, partly as a patient, partly for the purpose of obtaining a thorough knowledge of the same."

He has divided the book proper into four parts, and has annexed to these a few notes on climatic health-resorts. A map showing the position of the principal springs is added, thus indicating the nature of the work, which is that of a guide-book. This map, however, presents certain peculiarities attesting the author's knowledge of languages, it is true, but, on the other hand, marring somewhat the harmonious effect which geographical appellations are expected to produce. For behold, we find the German names of cities, rivers, lakes, etc., in the good old Teuton idiom; we find, however, some Belgian and Italian names paraphrased into German, but certain well-known islands are called Sicily and Sardinia in plain English, and certain familiar seas are called North Sea and Tyrrhenian, and the Mediterranean and Adriatic glory in English names. On the other hand, some French towns are still recognizable as such even to the purely Gallic eye. We notice an isolated attempt to anglicize Cöln into a familiar Cologne, but here the author's efforts apparently ceased and he relapsed at once into confusing German. It is to be hoped that the next edition of this book will see a map constructed on a uniform system of geography, and governed by monolinguistic principles.

Part I. is confined to some general remarks on watering-places and the use of mineral waters. In the second part we are given a topographical review of the watering-places. Then comes a section on the chemical composition and therapeutical application of the mineral waters, followed by the last part, which treats of climatological and balneological matters.

The author's style is pleasing, often sprightly, and creditably devoid of clumsy and puzzling Germanisms, which are so apt to creep into American books emanating from Teuton pens. Patients intending to go abroad may be advised to provide themselves with Gutmann's guide-book, and physicians will do well to glance over its pages for useful information.

Pasteur's Theory of Vaccination.—Says a correspondent of *The Lancet:* "The last two meetings of the Academy of Medicine have been rendered interesting by communications from M. Pasteur. Recent experiments with the virus which gives rise to the cholera of fowls have led the eminent biologist to conclusions respecting the variola and vaccinia which are of the very highest importance. Vaccine matter, says M. Pasteur, is nothing else than attenuated or diluted variolous virus, and it is unnecessary that it should pass through intermediate organisms. The experiments tend to prove that a weak dose of specific virus gives rise to a mitigated form of disease, which, however, is protective against the occurrence of the disease in its ordinary evolution. Should these views be justified by future research, and should their application be extended to other diseases, a new light will be thrown on the pathology of zymotic affections, and their prophylaxis rendered a matter of certainty."

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 24, 1880.

Dr. A. E. M. Purdy, President, in the Chair.

The Society was called to order at 8 p.m., and the minutes of the last stated meeting were read by the Secretary, Dr. F. A. Castle.

THE CLINICAL HISTORY OF A CASE OF LEPROSY, WITH REMARKS.

Dr. Sturgis read the notes of a case, which had been under the care of Dr. H. G. Piffard and himself. A male patient, past middle age, with negative family history, resided, previous to 1862, in Mexico and Texas. He returned to the State of New York in 1865. In 1874, the patient first noticed an eruption, maculæ, varying in size and of a reddish color that disappeared upon treatment, and he was not again troubled until 1876, when the maculæ reappeared and remained about one year. At some time during that period the patient's eyebrows fell out. In 1878, a tubercular eruption appeared upon the forehead. The legs had been swollen very large. He was admitted to Charity Hospital in October, 1878, where he submitted to a variety of treatment; took arsenic, mercurials, and also quite freely of gurjun balsam, but all remedies seemed to be ineffectual. In December, 1879, the tubercles had increased very much, had appeared upon the chin and the neck; the front part of the body was free, the upper two-thirds of the back were free except from melanotic stains. The skin on anterior aspect of the arms was thickened and contained numerous tubercles, varying in diameter from $\frac{1}{10}$ to $\frac{1}{4}$ of an inch, elevated, completely insensible. Neither hemorrhage nor pain followed the insertion of a pin the whole length into these thickened and tuberculous parts. The skin of both knees was thickened—extending down to the ankles, and the feet and hands were purple. The use of chaulmoogra oil was then begun, ♏vi. t.i.d., internally, and on ointment (25 per cent.) was used externally. The patient improved under its use, the noteworthy point being that the subcellular infiltration diminished and the tubercles were not so prominent as heretofore. There being no disturbance produced by the oil, it was continued, and the dose internally increased to ♏viii., with the ointment as previously applied. About the 20th of January, 1880, the patient had diarrhœa sufficient to cause the discontinuance of the oil, but it was resumed on the 22d, and soon after increased to ♏x. t.i.d., internally, and early in February the ointment was discontinued, and the clear oil applied externally. On March 15th the analgesia seemed to have returned, and again a pin could be run into the thickened portions of skin to the distance of half an inch without producing any sensation. March 29th.—Treatment continued. Tubercles over body softer and smaller; infiltration of skin less. Numbness still present, but less than at the last note. No disturbance from the use of the medicine. May 1st.—The tubercles still getting smaller and softer. On the 15th the freedom in motion of the skin almost normal; local anæsthesia had nearly disappeared. Treatment continued up to present date. (Patient exhibited.)

Dr. H. G. Piffard remarked that one interesting feature in the clinical history of the case was that while the patient was not taking the medicine last used, the disease began to return. One of the characteristics of this, as of other cases, was the cutaneous anæsthesia, complete in some parts. For instance, at one time the patient could run a pin into his hand nearly up to its head without producing any sensation, and the anæsthesia, which had disappeared while using the chaulmoogra oil, began to return while the oil was discontinued. [The supply in the hospital at one time gave out, and Parke, Davis & Co. of Detroit, Mich., forwarded three pounds for special use.]

Dr. Piffard then made some remarks concerning leprosy, with special reference to its history, morbid anatomy, etiology, symptoms, and treatment. The disease was of ancient origin. It was, however, probable that the term leprosy, used in the Bible, included a number of diseases besides that illustrated in the patient presented. The first to give a distinct account of leprosy, one by which it could be recognized, were the Greeks, but they did it under the name elephantiasis. The Arabians of the tenth, eleventh, twelfth, and thirteenth centuries gave a description of the disease which they called lepra. They have an entirely different disease which they call elephantiasis, consequently the term elephantiasis is likely to lead to confusion. The elephantiasis of the Arabians, characterized by great hypertrophy of the skin, is an affection quite different from true leprosy, which presents three marked varieties, known as the maculæ, the anæsthetic, and the tubercular. Occasionally cases occur which for many years exhibit the same character of lesion; for instance and by preference the maculæ, while in other cases the anæsthesia will be the leading feature; and in yet other cases there is slight maculation, possibly some anæsthesia, and a good deal of the tubercular element developed. As a rule all the varieties are illustrated in one case—as in the patient exhibited.

The morbid anatomy, briefly stated, consists in connective-tissue proliferation which affects the skin and the nerves. The tubercles are the result of the same change. The nerves and the skin are infiltrated with small round cells. The first physical sign is enlargement of the nerve-trunk affected, that most frequently involved being the ulnar nerve, and after that the nerves of the lower extremities. The ulnar nerve usually becomes very much enlarged by the infiltration, with small round cells everywhere within the sheath. Pressure upon the nerve-fibres is produced in that manner so as to cause pain, and pain is one of the earliest among the symptoms of leprosy. After a time the pressure is so great that the nerve-fibres are destroyed, the first change doubtless being a fatty degeneration of the white substance of Schwaan, finally the axis-cylinders, and at last, instead of a nerve-trunk, there exists a mere cord of sclerosed tissue, the ulnar being reduced in size from that of the little finger to that of a crow-quill. The changes are: first, proliferation, second, atrophy and disappearance of nerve-matter. The symptoms, therefore, are readily explained: first hyperæsthesia, second, anæsthesia. But leprosy does not always present the same symptoms at the beginning. It is a disease which may not appear until long after it has been contracted. In the case reported the disease did not appear until several years after the patient travelled in countries where it exists endemically, and where doubtless he contracted the affection. The first symptoms are not distinctive, the patient having, perhaps, some malaise, etc., later maculæ, or the maculæ may appear first upon any part of the body, usually upon the back part of the chest; or instead of maculæ he may have bullæ, and those cases, as a rule, are the ones in which the anæsthesia is most marked subsequently; or the disease may first exhibit itself as tubercles upon the face and other parts of the body. The disease, as a rule, gradually progresses until the three varieties mentioned can be seen in the same case. The tubercles are frequently stationary for some time, perhaps two years, and then gradually subside. In some cases suppuration occurs, abscesses form, and the tubercles disappear in that manner; but as a rule they disappear gradually and through the process of fatty degeneration and absorption. At the same time that some of the tubercles are disappearing others may be forming in the immediate neighborhood.

During the stage of hyperæsthesia the parts affected swell enormously, a limb reaching, perhaps, twice its normal size, the integument is stretched and shining; but the pain gradually disappears, the swelling gradually diminishes, the skin becomes whiter, and a little furrow occurs, perhaps across the dorsum of the distal phalanges of the fingers, not at the joint, but at some other point, and the furrow deepens, until after a time the patient some day notices that the tip of his finger is gone. The same changes may occur upon the toes. The gradual absorption of the bony tissue is more like the process of caries than necrosis, and may result, as in one case seen (illustrated by photographs), all the fingers and a portion of the metacarpal bones on the left hand were removed, the toes and a portion of the metatarsus on the left leg, and the right foot and leg were diseased still more than the left. The disease does not seem to be directly fatal in a majority of cases. As a rule, death is caused by some intercurrent disease, such as pulmonary, gastro-intestinal, etc. The average duration of life, as stated by Professors Danielssen and Boeck, is from twelve to fifteen years.

With reference to etiology, the history of leprosy in the Sandwich Islands leads one to the opinion that the disease is contagious. There are several thousands of lepers there, where the disease, several years ago, was not known.

The late Dr. Bulkley reported one case occurring in a person who had never been out of the State of New York, and in his diagnosis he was sustained by Boeck, of Christiana, Sweden. But the disease is not contagious from simple contact or through emanations from the body. Quite a number of cases have been traced to vaccination. It is believed to be hereditary, and there is considerable reason to suppose that such is the case. However, the etiology of the affection is decidedly uncertain.

With regard to treatment, the tubercles can almost always be caused to disappear by the application of some irritating substance, such as iodine ointment, chaulmoogra oil, etc. Cardol has been used on the anæsthetic patches with good results, as well as on the tubercles. Cleanliness is important. The three drugs which seem to have been of some service in the treatment of leprosy are nitrate of silver, as recommended in the "U. S. Navy Reports," nux vomica, which has appeared lately in a Tonquin remedy called hoang han, and chaulmoogra oil. If the disease is chiefly an affection of the nervous system, the use of nitrate of silver and strychnia preparations seems to promise the most benefit. Specimens of hoang han, hyrocolyte Asiatica, cardol, chaulmoogra, were exhibited, together with several photographs.

Dr. Samuel Sherwell, of Brooklyn, referred to a case under his care, and which had been reported in the *Archives of Dermatology* for April, 1880. An interesting item in the clinical history of the case was the occurrence of measles while the leprosy was steadily progressing.

Dr. G. H. Fox exhibited some photographs of cases of leprosy occurring in the Sandwich Islands. He thought the prognosis in cases of tubercular leprosy was not at all favorable. The duration of the life of a leper varied considerably, according to the predominating variety of the disease; the average was about twelve years, but with the macular variety the patient might live fifteen or twenty years; while with the tubercular variety he rarely lived more than nine years. With reference to the patient exhibited, Dr. Fox did not feel sanguine concerning a cure being effected.

Dr. Sturgis remarked that his expectations were not very great with reference to prognosis in the case brought before the Society. There had been a marked improvement, but as to its being permanent he was very doubtful.

Dr. Sherwell remarked that the manifestations of the disease were very much less than they were six months ago. The question of the occurrence of eye lesions in leprosy was raised, and Dr. Sturgis referred to Hanson and Ole Bull, who had described diseases of the eyelids and iritis associated with leprosy. The larynx, also, was sometimes entirely destroyed by the disease. Of other internal lesions he had no knowledge.

Dr. J. C. Peters presented a report as delegate to the National Pharmacopœial Convention.

The Comitia Minora was authorized to appoint the allotted number of delegates to the American Medical Association.

Dr. C. R. Agnew called from the table the portion of the report of the Comitia Minora concerning the application of Mrs. Clara L. Black for membership, and after some discussion the recommendation of the Comitia, that she be admitted to membership, was adopted by a vote of ayes 38, nays 11.

The Society then adjourned.

◆

THE NEW YORK SURGICAL SOCIETY.

Stated Meeting, March 9, 1880.

Dr. H. B. Sands, President, in the Chair.

Dr. Frank H. Hamilton presented specimens of supposed

FRACTURE OF THE HUMERAL EPICONDYLES,

received from Dr. Zuckerkandl, prosector in the University of Vienna.

The President referred to illustration of fracture of the external condyle and remarks upon two cases made in Gurlt's "Surgery." In one of the cases the fracture was spoken of and illustrated as fracture of the epicondyle not involving the lesser head. The other was spoken of as extending a short way through the articular surface, therefore not an example of pure epicondyloid fracture.

Dr. Hamilton remarked that the point which he had made was that it was so small it would escape observation clinically, and further, that it had not been shown by autopsy that it ever occurred.

Dr. L. A. Stimson remarked that he could not understand how fracture of the external epicondyle could be produced except in a person under sixteen years of age.

Both the external lateral ligament and the muscular attachments extend beyond the limits of the epicondyle, and fracture could occur only by tearing off these firm attachments to the bone.

Dr. T. M. Markoe had no doubt that fracture of the internal epicondyle could occur, but with regard to the external epicondyle, he had always had the conviction that it could not be broken off by external violence. It was an eminence simply rather than a prominence, and it seemed to him to be simply impossible to fracture except by exceedingly violent action of the ligaments and the muscles.

Moreover, in the bone of the young child the eminence or elevation known as the epicondyle was not only less than in the adult bone, but it was even dome-like almost, and the bony part which united the capitulum was exceedingly small, and it was very late in uniting with the remainder of the bone. Of course, it was only an impression, but he was not able to conceive how in either a child or an adult this fracture could take place, and he did not think the specimen exhibited was at all conclusive upon that point.

Dr. Lange referred to a case in which there was complete separation of both epicondyles as the result of injury. The patient was a boy ten years of age, who received a compound fracture of the elbow-joint.

There was almost complete separation of the articular part of the epiphysis, it being thrown almost completely out of the joint, and was held only by some small fibres. The epicondyles were in connection with the diaphysis, through the periosteum and the ligamentous structures, yet separated. He removed the lower end of the diaphysis and the articular part of the epiphysis, and the patient made a good recovery. The specimen did not show the epicondyles as they were left in connection with the periosteum, and assisted in giving shape to the newly formed extremity of the humerus. He thought it was a case which showed clearly that it was possible for the epicondyles to be separated in a young person, that is, before bony union had taken place.

Dr. Hamilton said that he had not understood that its possibility had been denied, but simply that the occurrence had not been proven.

Dr. Markoe thought that, in estimating all these anatomical points with reference to fractures, we should exclude from our study such cases as that to which Dr. Lange had referred. Certainly he could conceive that in a compound fracture the bones might be so broken that both epicondyles might be separated; and a musket-ball might have done the same thing; but the occurrence of fracture by (any other known?) violence was not explained by such cases. He thought that way of looking at the question should be borne in mind.

Dr. Hamilton remarked that that was precisely what was demanded, namely, the evidence of simple uncomplicated fracture, the occurrence of which he thought had not yet been proven.

Dr. Lange remarked that in his case there was no injury of any of the bones of the joint except as mentioned, and the surfaces in the specimen were smooth, showing that there had been a separation in the connecting cartilaginous structure.

Dr. Stimson remarked that he had an epicondyle unossified at the age of sixteen.

Dr. McBurney referred to a dissecting-room specimen to which a student directed his attention. It was a movable fragment over one internal condyle, and upon examining the other arm a precisely similar movable fragment was found at a corresponding point. In dissecting both arms it was found that they were fragments of bone, and that they corresponded precisely in appearance to the epicondyles, and gave origin to the flexor muscles of the forearm. He could very readily understand that if the person had received an injury about the elbow, followed by tenderness, it very probably would have been regarded as a case of fracture. It was evidently an old condition, and he thought it quite probable that it had existed during the man's life.

COMPOUND DISLOCATION OF BOTH BONES OF THE FOREARM UPWARD.

Dr. **Erskine Mason** reported two cases of complete dislocation of both bones of the forearm outward.

In one case the patient was a girl, seven years old, who, while climbing up into a closet, fell and received the injury, which, when Dr. Mason arrived a few hours afterward in consultation with Dr. Dew, was clearly marked. How she struck, the patient was unable to say.

The other case occurred in a boy twelve years of age, who came into Roosevelt Hospital on the 25th of February, 1876. The only history obtained was that he fell over the rocks, received the injury, and was brought at once to the hospital. The palm of the left hand was covered with dirt, while the right hand was clean. There was no difficulty in reducing the dislocation in either case. These were the third and fourth cases of the kind with which he had met. The first was in Bellevue Hospital a few years ago, and occurred in a young man. The second was an old dislocation which he saw in Dr. Hamilton's office.

ABSCESS IN THE UPPER PORTION OF THE TIBIA.

Dr. **L. A. Stimson** reported a case as follows: The patient was a boy fifteen years old. When thirteen years of age he was attacked by severe pain in the right tibia, which lasted several weeks, subsided, recurred at the end of six months, again subsided, and again recurred six months later, when Dr. Stimson saw him for the first time. The upper part of the leg was then swollen, the swelling extending downward along the central part of the tibia, and the soft parts gave the sensation of false fluctuation. The bone was evidently enlarged in its circumference, and there was localized tenderness and a ridge about the site of it. After rest in bed and the application of cotton and a bandage, the pain disappeared and the boy went home. Five or six months afterward he was again seized with pain in the same bone, and all the previous symptoms returned. There was a distinct localized point of maximum tenderness upon the inner surface of the tibia, about three inches below the articular edge. Although he suspected central disease he temporized and put the boy in bed, covered the limb with cotton, made pressure by means of a bandage, and awaited further development. At the end of three or four days the pain upon the inner side of the tibia had diminished, and about a week after he was first seen he was taken with severe pain on the outer side of the tibia, at the same level. A distinct swelling was then found between the tibia and fibula, at a corresponding point.

On the following morning he cut down upon the bone, found the periosteum loosened and very much thickened, fully one-quarter of an inch thick, soft and gelatinous, very much like the tissue about a strumous joint. A crucial incision was made and the periosteum stripped up, and a trephine made to enter the tibia about three-fourths of an inch, where a cavity was encountered, from which came two or three drachms of pus. The boy went on to rapid recovery.

The point of interest in the case was the following: Might not abscess of that kind be the starting-point of many of the cases of bone disease, which come under observation in dispensaries and hospitals?

In looking through text-books on surgery, he had not found any testimony on the subject; but in reviewing some special writings, particularly Prof. Markoe's book on diseases of the bones, he had found the subject thoroughly discussed, and the possibility of caries arising in this manner seemed to be perfectly well demonstrated. If that was true, early trephining in bone disease should, perhaps, be employed, much more than it is at present, as a preventive of the obstinate and deforming diseases which follow if the disease goes on unchecked. Some of the best results had also been obtained when no pus was found, and the operation, with antiseptic precautions, was certainly not a dangerous one.

Dr. **Morgan Smith**, of Connecticut, had reported, in *Hay's Journal*, in 1838, three or four cases of what, at the present time, would be described as acute osteomyelitis, in which he perforated the bone with a drill, giving exit to pus, and thereby giving relief immediately to all the symptoms. In every case recovery took place without necrosis. The possibility of spontaneous evacuation of the pus had been discussed by Chassaignac in a posthumous work published in the *Bulletin of the Society of Surgery*, in 1879, and the cause which produced it was attributed entirely to the perforation of the periosteum from without inward, and not from within outward.

Dr. **Stimson** thought that the abscess, in his case, was in the medullary cavity, and presumed that there was a diaphragm which cut the pus off from the lower part of the canal.

Dr. **Hamilton** asked, Why should not the same method be adopted long before the existence of pus was expected, in cases of impending destruction, for example, of the epiphysis in so-called white swelling? Would not an early operation prevent a certain proportion of cases of chronic osteo-myelitis of the epiphysis?

The **President** remarked that the French had already resorted to the early treatment by means of the Pacquelin cautery.

Dr. **Stimson** remarked that Bryant had reported several cases in which he trephined in the early stages, and with good results (*Guy's Hospital Reports*, 1879).

Dr. **Lange** remarked that the plan had been recommended by Kocher, of Berne. It was also adopted, when he was Prof. Esmarch's assistant, and he had seen him treat a number of cases of white swelling in that manner. It seemed to Dr. Lange that it was a method that could be resorted to with great benefit in the early stages, especially with regard to pain, which disappeared almost instantly on making the ignipuncture.

Volkmann and Luecke had practised and recommended opening the epiphyseal part of bones without opening joints by making the operation extra-articular, and so remove all the diseased parts. The intention was to effect a cure without disturbing the joint, and they had been successful in several cases.

Dr. **Stimson** thought that abscess did not occur with such frequency in the epiphysis as in the expanded portion of the bone.

Dr. Hamilton said that when he used the term epiphysis, it was in the sense in which it was commonly employed; but he meant to speak of the more expanded upper portion of the tibia or lower portion of the femur.

FAVUS OF THE PENIS.

The President reported a case as follows: About a week ago he was consulted by a physician, who came from Connecticut, to obtain his opinion with regard to what he called two ulcers upon his penis, for the existence of which he could give no explanation. He was a married man, and said that if he had contracted any disease it must have been from his wife, whom he had no reason whatever to suspect. He said the sores were upon the outer surface of the foreskin, near the glans, and that they had appeared about a month after connection, and three weeks previous to his visit to Dr. Sands. At first he thought nothing of them, but as they persisted and increased in size he became alarmed and sought an explanation. At first, when questioned, he had no recollection of having received any injury, but soon recalled the fact that he had received a slight scratch upon his penis from a pet cat which was in the habit of getting into bed with himself and wife every morning. Upon examining the penis Dr. Sands found two well-marked patches of favus, about a quarter of an inch in diameter, which had been mistaken for ulcers. A portion of one of the crusts was removed and placed under the microscope, when the nature of the disease was clearly revealed. The crusts were removed and a solution of bichloride of mercury applied.

DIPHTHERIA OF THE PENIS.

Dr. Lange gave the following history of a case: About one week previously he was called in consultation to see a Jewish child three weeks old, which had been circumcised. At the time the operation was performed there was another child suffering from a grave type of diphtheria of the throat, soon after terminating fatally, and yet another child was subsequently attacked by the disease. In the case he was called to see he found a diphtheritic membrane covering the cut preputial surface, and two patches upon the scrotum, apparently due to coming in contact with the glans. The surface had already been cauterized several times, and Dr. Lange applied the actual cautery, as strong as was admissible, without much effect. There was no evidence of the formation of a line of demarcation. To be sure the process was essentially at a standstill, but the penis remained a swollen and infiltrated mass. The child was not very badly nourished, but was somewhat weak, had much trouble in urinating, and the diphtheritic process was going into the urethra, causing slight adhesions of the lips of the meatus and great pain. He thought such operations should not be done during the prevalence of diphtheria in the same house, and asked the Society if further cauterization would be beneficial, and also for further suggestions regarding treatment.

Dr. Robert H. Chase has been appointed resident physician at the Norristown State Hospital for the Insane. Miss Mary H. Stimsom was elected female house physician, but declined on account of her health.

THE CHICAGO GYNECOLOGICAL SOCIETY.

Meeting of May 21, 1880.

THE MANAGEMENT OF THE UTERUS AFTER LABOR.

Prof. J. H. Etheridge read a paper on this subject. He was certain the condition of the uterus after labor was too little studied. As a consequence much permanent uterine disease resulted, much more, in fact, than was usually supposed by the profession. He had tabulated the last hundred consecutive gynecological cases which had occurred in his dispensary practice, with a view to ascertain the causes of the ailments. There were excluded only virgins and women suffering from malignant and venereal diseases. The result of this enumeration, with the diagnoses, was as follows:

Causes.		*Diagnoses.*	
Confinements........	50	Hypertrophy........	34
Miscarriages.........	28	Uterine catarrh......	53
Hard work..........	5	Lacerated cervix.....	9
Unknown...........	17	Prolapsus..	2
		Metrorrhagia........	1
		Retroflexion.........	1
	100		100

Thus, 78 per cent. of these cases followed closely gestation, partial or complete.

The duty of the obstetrician to his lying-in patient did not end till involution of the uterus was complete. This required a period of six to eight weeks. The process was fatty degeneration and absorption. Interference with this process led to uterine disease, in fact anything that lowered the normal health-standard. Faulty nutrition did it; diathesis did it; *e. g.*, the rheumatic, strumous, and gouty. He spoke with confidence on this point from having cured many patients with anti-rheumatic, anti-gouty, or anti-strumous remedies. Anæmia from loss of blood at confinement often interfered with the process of involution. Subinvolution was common in women whose anæmia dated from confinement. Constipation interfered with involution; laceration of the cervix did so likewise. Other causes were bad hygiene and depressing emotions; another still was too early resumption of the sexual act, and another was the condition generally known as neurasthenia.

The treatment of such cases should be general and local. Dyspepsia and constipation must be reduced to a minimum: the diathetic state corrected, if possible; anæmia relieved. For the neurasthenia, massage, good diet, and all the elements of good hygiene, with perhaps electricity, were the best measures.

For local treatment, lacerations should be closed, prolapsus relieved by well-fitting mechanical supports; ergot should be given in small and repeated doses by mouth or rectum (*e. g.*, 10 to 15 drops, four to six times daily, by the mouth); hot-water injections per vaginam—one to two gallons of very hot water two or three times a day; and when impossible per vaginam, then fewer and smaller injections per rectum. Another measure of benefit was, for subinvolution in chronic cases, the use of tents for repeated distention of the uterus; the slippery elm, sea-tangle or tupelo might be used. Uterine massage, he thought, was a valuable remedy.

In the discussion which followed, Dr. E. said it was claimed that hot-water injections produced temporary anæmia, followed by increased turgescence. This as true only when they were resorted to infrequently. f taken three or four times a day, the blanching ffect of one injection remained till the next.

For the constipation accompanying dyspepsia in many cases, he thought nothing better than laxave doses of mineral waters. A woman should be orizontal and resting most of the time after connement till after the fundus uteri ceased to rise bove the pubes.

Correspondence.

DOES CHLOROFORM EVER CAUSE DIABETES?

A Question to the Medical Profession.

To the Editor of The Medical Record.

EAR SIR:—I wish to lay before you, and the medical rofession generally, the facts of a case occurring in y practice which is of great interest to myself, and hich I hope may be so to others, as it is, so far as I now, unique.

On the *tenth* day of April last, I was called to see . C., a healthy boy, three years and nine months of ge, who had the misfortune to tumble from a fence d injure his elbow-joint. He was very much frightned, and the slightest manipulation of the affected rm seemed to cause him great pain, and at the olicitation of his mother I administered a little hloroform—not enough to produce complete unconciousness, but just sufficient to render him a little uiet so that I could make the necessary examinaion. The external condyle of the right humerus as broken off, and for lack of a proper splint I did up temporarily in one of pasteboard. I did not isturb it again until the thirteenth, at which time I gain found it necessary to resort to the anæsthetic. his time the administration of the chloroform was trusted to the father of the child, and for about vo minutes near the close of the operation, he was retty thoroughly under its influence, though he raled quickly, and there were no worse symptoms subequently than a considerable degree of gastric irriation, as evidenced by vomiting during the night ollowing. From this time the child seemed to be oing well, and I removed the splints, for the purpose f manipulating the joint to prevent stiffening, on e 21st, eleven days after the injury, and again relaced them. At this time the child's mother remarked to me that Harry seemed to be passing an nusual amount of urine. Otherwise he seemed well, laying about as usual, and with a tolerably good ppetite. I made some inquiry as to the character f the urine voided, and as he appeared to be in a omewhat nervous condition, I attributed the increased flow of urine to that circumstance. I next w him on the 28th, when I again removed the lints and manipulated the arm as before, replaced em, and instructed the mother to remove them very day and use passive motion. At this time the ild, to all appearance, was doing well, except that e was somewhat constipated and still passing too reat a quantity of water. I left some simple remeies for him. The arm was gaining nicely and I saw im no more until May 8th, upon which day his ther called at my office and requested me to visit is child, remarking that his wife seemed to be great-, and as he thought, needlessly alarmed about him. I accordingly went and found a great and decided change in his condition. He was restless, had evidently been losing flesh and color, respiration short and sighing, but there were no râles or other physical signs of pneumonic trouble. The temperature was normal, and the pulse, though excessively weak, was in other respects natural. Bowels obstinately constipated; thirst considerable, and urine still very abundant. I now, for the first time, suspected the *real* cause of the excessive secretion of urine, but as none of it was at this time procurable, I could not verify my diagnosis. I prescribed such remedies as seemed indicated to relieve his constipation and the other symptoms, and did not see him again until about 3 o'clock the next morning, at which time I was called in great haste, as he appeared to be dying.

I found him very restless, frequently screaming as if in great agony, with cold extremities, pulse scarcely perceptible at times, respiration short and sighing, and he was evidently fast passing into a state of collapse. His mind was clear, and remained so to the last. I saw the utter hopelessness of his condition, and to allay his evident agony, administered morphia at sufficiently frequent intervals to keep him quiet.

At this time I procured about 4 oz. of his urine, which was frothy, light colored, and of slightly acid reaction.

The specimen examined subsequently showed a sp. grav. of 1034, and with Luton's test—kindly applied for me by Dr. Edward H. Parker, of Poughkeepsie—abundant evidence of sugar. The child lingered until about eleven o'clock the following night, when he quietly expired.

The mother—a lady of more than ordinary intelligence—had told me previously of the case of an aunt who had died in St. Luke's Hospital, New York, after operation under ether, not from the effects of the surgical procedure, but, as she expressed it, from "her blood turning to water" as a consequence of the anæsthetic. My friend, Dr. W. Washburn, has kindly examined the hospital record of this case, and ascertained that she never fully recovered from the shock of the operation, had *suppression* of urine, and died comatose two days after, autopsy showing chronic parenchymatous degeneration of the kidneys. So the mother had evidently received a wrong impression, but when her child's condition became apparent, very naturally reverted to the *chloroform* as the *cause* of the trouble. I have questioned her minutely and repeatedly in regard to the state of her child's health, and especially as to the condition of his urine, its quantity, etc., previously to the anæsthesia; but she persists in declaring that he had always been healthy, and had never shown a symptom of diabetic trouble until after the use of chloroform, but, on the contrary, she had noticed on several occasions (and she is a close observer, and had been always most solicitous concerning her child's health), that his urine was a little *scanty*, and had administered some simple remedies for it. She says, also, that the increased flow of urine commenced *immediately after the last administration of chloroform*, so that she was obliged to take him up several times during the following night to allow him to urinate, a thing which *never* had occurred before.

And now for the question of interest in the case.

Has the anæsthetic use of chloroform ever been known to *cause diabetes mellitus?* I can find no allusion to such in any of the books to which I have had access, nor have any of my professional brethren to whom I have made known the facts of the case found a parallel, either in their experience or their reading. Did the chloroform in my case *cause* the diabetes? *might* it have caused it? or did it merely precipitate an already existing disease?

The disease, in my case, certainly run a most rapid course, even for so young a subject, for, from the time of the last administration of the chloroform, from which date the *observable* signs of the disease *certainly* had their beginning, to the time of his death, was only twenty-six days. "Sit lux."

Respectfully,
Geo. Huntington, M.D.

La Grangeville, N. Y., June 18, 1880.

PROVIDENT DISPENSARIES.

To the Editor of The Medical Record.

Sir—There is a young lady in this city, a doctor of medicine, who has recently displayed much enterprise and energy of character. These qualities had previously been trained by a homœopathic education, and they now appear to be leavened, as it were, by philanthropic aspirations.

Influenced by a desire to relieve the physical, and particularly uterine, troubles of her own sex, she has established a dispensary, where, for the small sum of twenty-five cents, her services will be rendered to women and children. It is not distinctly stated that this sum represents the value of the service given, but it is all that will be asked. This lady, though thus bold and unselfish in her peculiar philanthropy, is not alone or the first in it. From London and from Salt Lake City similar notices of low fees and lofty endeavor have startled the profession. Indeed, the plan of small fees and many of them is evidently spreading and deserves attention.

Twenty-five cent dispensaries are the offshoot of medical competition, and the abuses that have become a part of the regular dispensary system. That they degrade the practitioner without elevating the patient or improving the system of charity, goes without saying. Undertaken, as a rule, by irresponsible parties, they serve to cloak incompetency and pecuniary ambition under the mantle of philanthropy. They are liable to innumerable abuses, and on this account alone can never, even under responsible management, help to solve the problem of the proper application of medical charity. Nevertheless, they are the legitimate outgrowth of the present dispensary system, and are liable to crop out as long as that remains unchanged. It is found, in dispensary practice, that a number of patients are willing, perhaps anxious, to pay fifteen or twenty-five cents, because they do not wish to be thought beggars, while a small sum is all they can afford to give. This class is a large one; added to those who could pay more or less, but will not, it amounts to more than half of those who visit dispensaries.

The problem, then, is how to utilize such contributions as these patients are able to make, so that they can receive medical treatment in a way satisfactory to themselves and not degrading to the medical profession.

I am of the opinion that the only practical solution of this problem is in the establishment of provident dispensaries. These should be mutual health associations, and should be adjuncts, and supplementary only to the regular dispensaries.

I am perfectly aware of the difficulties in the way of establishing such institutions. These difficulties, as well as the details of organization, have been often discussed in your columns. I am aware, too, that attempts have already been made, without success, to establish provident dispensaries in this city. Neverthless, this is the only plan having the least claim at practicability, by which it is possible to relieve materially the immense abuses in our medical charities. Besides, the prospects of success are better now than several years ago. Such institutions have been introduced into England, and have, after much trouble and opposition, attained a wide prevalence and popularity there. With us the existence of gross abuses in the bestowal of charity is now better known and more deeply felt. There is a population of from 100,000 to 200,000, at the least, now relying mostly on dispensaries, which could very well pay for its medical relief by the provident system. It requires only a membership of from 3,000 to 5,000 to make a provident dispensary self-supporting. There is no reason, therefore, in the nature of things, why these associations cannot be successfully organized.

We should not expect too much of them, however, at first. There is a certain improvidence among Americans, a fixed idea with each one that he will soon be richer and above the need of help, that will be hard to fight against. In England it is the old-style dispensaries that have been the worst enemies of the new; and much opposition, direct or indirect, must be expected from them here. Considerable money, therefore, would be needed to start the first ones.

Finally, allow me to say that I cannot insist too strongly on the suggestion already made, that all such dispensaries be under the control of the regular medical societies. Without this they would become rank with abuses and demoralizing alike to the profession and the public. With them, however, under such direction, we could hope in time for a great improvement in the distribution of medical charity.

General Practitioner.

New York, July 6, 1880.

Oleo-margarine unfavorably considered in France.—M. Riche has just presented a report to the Paris Academy of Medicine on the substitution of oleo-margarine for butter and lard in the preparation of food. The substance had been so highly praised that the French Minister of Commerce asked the Academy to investigate it. Numerous experiments were tried, chiefly upon patients in insane asylums. M. Riche's report shows that neither the attendants nor the patients bore well the substitution of oleo-margarine for butter; that the change of diet was injurious, because vegetable oils are more difficult to digest than animal oils.

The Night Medical Service of Paris.—Now that the night medical service has been established in this city, the statistics of this service in Paris, just published, may be of interest. They cover the first quarter of the present year. During that time 1847 visits were made, being an increase of 462 on the preceding year. The proportion of patients visited was: women, 48 per cent.; men, 35 per cent.; children under three years of age, 17 per cent. The diseases and accidents requiring assistance were: throat affections, 143; croup, 64; bronchitis, 143; intestinal derangements, 116; hepatic and nephritic colic, 55; strangulated hernia, 19; retention of urine, 22; hemorrhage, 78; wounds, 67; fractures and dislocations, 36; convulsions, 88; eruptive diseases, 57; confinements, 133.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending July 3, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

Transverse Depressions on the Nails.—For some time there has been a good deal of correspondence and comment on the subject of transverse depressions on the nails. It was asserted that whenever a person is sick it causes such a depression in the nails, and in this way insurance examiners, for instance, might know whether a person is telling the truth when he says he has always been well. Dr. Richard Budd now writes to the *Lancet* and says, that for thirty years he has had transverse depressions on his nails, and yet he has never been sick in his life.

Fowl-cholera.—M. Pasteur, having shown that fowl-cholera is due to a specific germ, now states that inoculation with a mild virus prevents the disease.

A New Ophthalmological Hospital has been established in Paris.

The Decline of the Use of Salicylic Acid in the Treatment of Rheumatism.—In a paper read by Dr. Greenhow before the Clinical Society of London, the question of the value of salicin and the salicylates of soda in the treatment of acute rheumatism was discussed. While admitting that these drugs gave great immediate relief, Dr. Greenhow stated that they did not lessen the complications of the disease, that they did not lessen the time when the patient was disabled, that they left him in a more than usual anæmic condition; and that they rarely lessened the hyperpyrexia. Several gentlemen agreed with Dr. G.'s views; more were inclined to think better of the drug than he, none asserted it to be a specific.

Trichinosis on the School Ship "Cornwall."—It is now stated that the supposed outbreak of trichinosis on board the "Cornwall" was not trichinosis at all. Dr. Colbold wrote a letter to the *Times*, denying that the epidemic was trichinosis, and is responsible for the assertion. His reasons, it must be confessed, are strong, and he is high authority. The announcement places some of the English medical journals, which accepted the conclusions of Mr. Power without reserve, and commented on the outbreak at great length, in an unpleasant position.

The Annual Meeting of the American Society of Microscopists will be held at Detroit, August 17, 1880.

Vaccination in France.—A bill has been introduced into the French Chamber making vaccination compulsory.

Medical Practitioners in France.—The proportion of medical practitioners to the population has been declining in France as well as in England and Wales, of late years. In France in 1846, there were 51 medical practitioners to each 100,000 of the population; in 1866, this proportion had declined to 48, and in 1876 to 40. This decline is chiefly among the "officers de santé." The cause of this decline in France is ascribed to the law which prevents the doctor from dispensing his own medicines. The professions of medicine and pharmacy are kept entirely distinct, to the great inconvenience, often, of medical men and the public.

Discussing Charity.—The tenth annual convention of the County Superintendents of the Poor, of this State, recently met in New York. The most important topic discussed was that of establishing a Bureau of Labor and Charities in every large town in the State. Such institutions have been in successful working in Syracuse, Poughkeepsie, and other places. A resolution was passed endorsing the system.

Pilocarpin as a Remedy for Baldness is gaining reputation among the laity. Stories of its virtues are going through the public press.

Steamers for Interstate Quarantine.—Four small, swift propellers are now being built at Pittsburg. They are rapidly approaching completion, and will soon depart for the South, where they are destined to play an important part in the sanitary condition of the Mississippi Valley, during the coming and subsequent summers, in carrying on a campaign against the spread of yellow fever. The boats were ordered by the National Board of Health. They will distribute provision and medicines to infected cities, and can be turned into hospitals. The flagship of the fleet is the *Benner;* she is named after the late Lieutenant Henry A. Benner, whose life was sacrificed during the last yellow fever visitation. Her cabin is devoid of staterooms forward, and the space, 14 by 50 feet, is to be taken up by thirty iron cots for patients. Aft of this space are two handsome apartments for the two doctors on board, and there are also accommodations for a crew of eight or ten. This vessel is for duty as a patrol, and for furnishing supplies to the following stations: Cairo, Memphis, and Vicksburg. As adjuncts to the *Benner* are three small, swift steel propellers—the *Picket*, *Lookout*, and *Patrol*. Each is 36 feet long, 7 feet beam, and 3½ feet hold. The boats must prove very fast. Their duty is to overhaul passing steamers, and to see that such are observing quarantine regulations.—*Nautical Gazette.*

Dr. Stephen Smith, of the National Board of Health, has gone South to Memphis and other places on a tour of inspection.

Breathing under Water.—Mr. Fleuss's invention, by which he is able to stay under water for one or two hours without any pumping in of air from outside, and without taking down any cumbersome apparatus with him, has at last been explained. His dress is much like that of ordinary divers, but the helmet has no connection with anything above. He takes down in the helmet a supply of compressed oxygen; this is allowed to escape slowly, and is diluted with the nitrogen in the case; the exhaled carbonic acid is breathed into a tube which passes into caustic soda, where it combines and is made innocuous. This process can be kept up for a long time without any inconvenience. The first time Mr. Fleuss made an experiment with his invention, he remained under water for over an hour.

The Registration of New York Physicians.—The books for registration under the new law of this State will be opened about the middle of July. As there will probably be about 3,000 persons to register in this county, within the ninety subsequent days, it would be well for physicians not to put the matter off too long.

Change in the Duties of the Censors of the County Society—The new registration law takes away most of the duties heretofore belonging to the censors of our County Society. In order not to have the office a sinecure, as well as for other reasons, it is proposed that the by-laws be so amended that the censors may be given the duty of watching the county registration books, and seeing that registration is properly carried out. The proposed action might well be imitated by other county societies.

Heidenhain's Theory of Mesmerism.—The distinguished physiologist, Prof. Heidenhain, has been investigating the subject of mesmerism, so called, and gives the following view of its pathology. The gray matter of the cerebrum (gray matter of the convolutions) is exhausted by certain fatiguing procedures, and thereby consciousness and will, as well as the regulation of reflex action are suspended. As a consequence, certain habitual motions (walking, speaking, writing) take place upon peripheral irritations, and sensual impressions in general, the excitation passing inward to the vasal ganglia and thence, avoiding the cortical region, to the periphery again. Naturally, through these channels, will such responses be obtained as are most frequently traversed by impulses, centripetal and centrifugal; hence, many will readily exhibit special movements in imitation, which in the case of others will not appear, or at least will be imitated with difficulty. Prof. Heidenhain finds three or four persons out of ten who are "mediums;" these do not necessarily belong to the class of hysterical, anæmic, or nervous.

There are certain special regions, such as the nape of the neck and the epigastrium, if these are stroked or excited with electricity, the patients begin at once to speak.

The Rot in Sheep has been very prevalent in England during the past few months. Sheep have died by thousands from it. Measures have been taken to investigate its cause and means of prevention.

The Free Swimming-Baths of New York.—These baths, which number half a dozen, are having an immense patronage. About 160,000 persons per week use them, one-third being females. The boys are particularly happy over their opportunities of free ablution. They at first made numerous attempts to go from one bath to another. These attempts developed the interesting physiological fact that bathing produces a prolonged tetanus of the peripheral circulation of the nose; if a boy is found to have a cold nose, therefore, he is at once rejected as being a "rounder."

Vacation.—This is the time for physicians to remember Sir Henry Holland's theory, that a doctor will increase his practice if he takes a month's vacation every year.

Co-operative Stores and Provident Dispensaries.—One of the Co-operative Store Associations in London has united a provident dispensary, a sick, benevolent, and burial fund to its other work, also a savings bank.

A New Morgue.—Plans for a new morgue at Bellevue Hospital have been drawn, and the erection of the building is probable.

Dr. Grant Bey.—Dr. Grant, an English physician who has for some years been practising in Cairo, and who has done much to give Egypt a reputation as a health resort, has been given the rank of miralay, or bey.

A Histological Laboratory is to be established in the Medical School of Paris under the direction, probably, of M. Cadiat, who is well known in France for his microscopical labors. This new laboratory is intended to be a substitute for the proposed chair of pathological anatomy which met with so much opposition.

The Chian Turpentine Cure for Cancer.—Mr. John Clay reports that he continues to get very satisfactory results from the Chian turpentine. The drug is being tried in some of the London hospitals. The trouble seems to be that no one but Mr. Clay is able to get hold of the right kind of Chian turpentine.

Another Pair of "Siamese Twins."—At Instow, North Devon, England, a woman has given birth to two females joined, or rather incorporated together, from the mammæ down to the abdomen. They are healthy, and perfect in every other respect, having each a head, a trunk, and two upper and lower extremities.

Seats for Shop-Girls.—Ninety houses in Dublin, within the past year, have provided seats for their shop assistants.

Lister.—The Degree of D.C.L. has recently been conferred on Joseph Lister, F.R.S., by Oxford University.

Hospital Sunday in London.—The annual collections for the hospitals and dispensaries of London, were taken up on June 12th and 13th. These hospital Saturday and Sunday collections have now been made for seven years, and form an important means of support to many of the 128 institutions for which they are intended. The depression in trade has embarrassed the work of many London hospitals, so that there are at present only 3,232 beds in daily use and available for the indigent sick. This gives but one bed to 1,237 of the population. The actual number of beds in the London hospitals, benefited by the Hospital Sunday Fund, is 5,531.

Dr. Amidon's Essay on Cerebral Localization, in which he endeavored to locate cortical motor centres by recording the rise of temperature over the skull during voluntary muscular exertion, has been discussed by the Paris Biological Society. M. Paul Bert complimented the author, and referred to his own researches upon the subject. Employing a thermo-electric pile with all necessary precautions, he found that talking in a loud voice caused an elevation in the temperature in the left anterior frontal region. He also found a rise in temperature in children, in the frontal region, at the moment of waking.

In examining the lateral regions of the skull over the motor centres, he was never able to observe any change in the temperature on muscular exertion. He suggested that the muscular exertion in the limbs may have been accompanied by contractions in the muscles of the head sufficient to cause the local rise in temperature.

It will strike the reader that M. Paul Bert, in discussing Dr. Amidon's paper, talked more of what M. Bert had done than of anything else. His explanation of Amidon's results is very far-fetched, to use the mildest term.

Milk as a Cause of Tuberculosis is the subject now being discussed among pathologists and sanitarians. The possibility of danger from tuberculous cows was first brought prominently forward by Mr. Fleming, in 1874. He then gave evidence to show that the milk of tuberculous cows could produce the disease in other animals, such as pigs, to whom it was given. This gentleman has recently read a paper on the same subject, bringing fresh facts to bear upon it. He stated that tuberculosis is on the increase, and that nearly five per cent. of cows are affected by it. It is especially prevalent among dairy cows.

According to Cohnheim's latest views and experiments, endorsed by Friedleinder, the intestinal tract is liable to direct infection through the agency of diseased cow's milk. This leads to phthisis mesenterica, so frequent in children. Adding thus the theoretical views of Cohnheim to the facts given by Fleming, and there is good cause for paying close attention to the subject, and perhaps keeping supervision over our dairies and slaughter-houses.

Medical Reform in France.—The doctors of Marseilles and the surrounding districts have sent a petition to the National Assembly asking for a number of changes and reforms. They beg that the distinction between doctor and "officier de santé" be now kept up, but that any "officier" be allowed to have the degree of doctor of medicine after seven years' practice, and the presentation of a thesis. They also ask for new regulations regarding the licensing of foreigners to practise medicine; they assert that medical expert testimony should be better paid. Finally, they urge the creation of a medical council of discipline, to be intrusted with maintaining the tradition, honor, and dignity of the profession.

Remarkable Course of a Bullet in a Gunshot Wound of the Chest.—Dr. W. C. Morse, of Eldora, Iowa, sends us a curious history under the above head. He was called last December to see a young lady who had attempted suicide by shooting herself with a revolver. A wound was discovered 3 inches above the left nipple and 2¾ inches to the left of the sternum. There was no wound of exit; a probe, passed in for two inches, showed that the direction of the bullet was upward and inward, so that the point of exit should have been, if the ball had continued its course, about the middle of the spine of the scapula. There was much dyspnœa, but only a little hemorrhage. The patient continued in tolerably good condition until the fourth day. She then complained of pain in the left side. Examination revealed the presence of the ball between the 9th and 10th ribs, and about 7 inches from the spinous process of the 9th dorsal vertebra. It was easily removed by an incision, and the patient made a good recovery.

Red Perspiration in the Axilla.—The same writer, Dr. Morse, says in regard to red perspiration in the axilla, that the cases of this condition are very common. Few, if any, fleshy people are exempt, although it is not by any means confined to this class. The axilla is seldom inhabited, he adds, without the hairs of the pubis being similarly affected. Its chief cause is lack of cleanliness, and the trouble is easily cured by means of mercurial ointment, compound zinc ointment, or carbolic acid soap and water.

The Lithophone is a new instrument recently presented by Dr. Jonathan Langhbert, at the Paris Academy of Medicine. It is constructed somewhat on the plan of Sir Henry Thomson's instrument. By it the slightest hard deposit in the bladder can be at once distinguished.

The Fasting Man.—Mr. H. S. Tanner, of Minneapolis, Minn., began a forty days' fast in this city June 28th, at 12.30 p.m. He failed to make arrangements with the Neurological Society, considering their conditions too exacting. He placed himself under several eclectic physicians, who undertook to watch him and keep account of his physical condition. On July 7th, the eighth day, he was said to have eaten nothing, and had apparently only gargled his mouth at intervals with water, drinking none. He had lost about fifteen pounds of flesh; his pulse was 77, and had been, at times, faster. It was pretty strong. The temperature and respiration were normal. The general physical condition appeared good. Mr. Tanner walked about the room occasionally, and conversed freely. Assuming that he had not taken any food, his condition was remarkable. It is unfortunate that under present circumstances the results will probably not be accepted by scientific men.

The Anglo-Indian Medical Service.—Much alarm was created last winter by the issuing of an order which cut off the heads of the Indian Medical Service, and seemed the beginning of an attempt to destroy it as a separate department. Indian and English journals were filled with protests against the possible injustice and calamity. The Indian Government, after keeping its medical officers in suspense for four months, has at last issued another order by which, in deference perhaps to public sentiment, the Medical Service has been partly reorganized. It makes the Service distinct and independent as before, but changes the classes of officers. On the whole, the order is a tolerably satisfactory one and greatly different from what had been expected. There is peace again.

Sanitation in Fashion.—A number of drawing-room lectures, on subjects pertaining to health, have recently been given to select audiences in Mayfair, London. Dr. Carpenter, Dr. Richardson, and other prominent men, have delivered the lectures, which have been received with much interest. The last lecture was by Mr. Ernest Hart, on the subject of "The Doctor in the Kitchen." Mr. Hart condemned strongly the excessive "meatiness" of the English diet, and advocated the use upon the table of more vegetables and fish. He condemned "roasting," in the English fashion, as an extravagant process, and advocated the use of ventilated closed stoves. He referred, of course, to the American stoves, which English housewives are too stupid to see the advantages of, or too conservative to adopt. Mr. Hart said that English bread is the best in the world. A number of other criticisms and suggestions were given, all of which seemed to please very much the Mayfair ladies.

As to this matter of the "Doctor in the Kitchen," it seems as though the functions of the physician was being extended a little too far. In the endeavor to make us cover every field of usefulness, the medical mind may be spread out too thin for utility. The general practitioner is now expected to be a good physician and surgeon, a competent sanitarian and a dispenser of all kinds of medical charity. It begins to look like cruelty when he is told that he ought to keep an eye on the kitchen, and know more concerning its dishes than the cook. A physician ought to see that his patients are properly fed, and he should know the delicacies that will do for invalid stomachs. But his province is the sick-room, not the pantry or the kitchen. Let him keep out of these except for purposes of private and personal satisfaction. The staff of Æsculapius is bound by two snakes—not by the *cordon bleu.*

The Thirty-Fourth Annual Meeting of the Ohio Medical Society took place at Cleveland, O.: Dr. John A. Murphy, President, in the chair. The session was opened in the afternoon with prayer by Rev. Dr. G. L. Robertson. Mayor Herrick delivered an address of welcome, in which he spoke of the great advances which medical science had made during the present century. After some routine business had been transacted, and a few papers read, the Society adjourned to visit the Cleveland Hospital for the Insane. A number of speeches were here made, including an address of welcome by the medical superintendent, Dr. Strong. On the second day, the regular committees were appointed, and forty-eight new members were enrolled, including one woman.

The Committee on Obituary reported the deaths of seven members during the past year.

Reports of the Special Committees on Progress of Medicine were presented. Eighteen papers were read. The following are their titles: "Diseases of the Nervous System," by Dr. D. A. Morse; "Therapeutics, Past and Present," by Dr. E. H. Hyatt; "Insanity," by Dr. J. C. Kennedy; "Drinking Waters of the Cities of Ohio," by Dr. W. J. Scott; "Cystic Degeneration," by Dr. J. N. Snyder; "Heredity," by Dr. J. H. Clark; "Physiological Action and Therapy of Gelseminum Sempervirens," by Dr. C. E. Beardsley; "Epidemic Diseases of Ohio," by Dr. A. Hurd; "Gynecology," by Dr. T. A. Kenny; "The Possibilities of Perfecting the Human Species," by Dr. C. Smith; "Post-Nasal Catarrh," by Dr. J. H. Lowman; "Non-Malignant Tumors of the Female Breast," by Dr. C. S. Muscroft; "Dysmenorrhœa," by Dr. M. C. Cuykendall; "Laryngeal Phthisis," by Dr. G. T. Whittaker; "Syphilis," by Dr. J. H. Pooley; "Idiopathic Chronic Catarrhal Laryngitis," by Dr. Bernard Tauber; "Progress of Ophthalmology," by Dr. H. G. Cornwell.

The following officers were elected for the ensuing year: President, Dr. E. H. Hyatt; Vice-Presidents, Drs. C. Falconer, J. C. Hubbard, H. J. Donahue, and R. L. Sweeney; Secretary, Dr. Baldwin; Assistant Secretary, Dr. A. C. A. Kirkley; Treasurer and Librarian, Dr. T. W. Jones.

The annual address by the President was a very able one. He referred to the prosperous condition of the Society, and urged the passage of laws establishing a State Health Board, and regulating the practice of medicine. On the third day considerable business was transacted; the most important measure was the appointment of a committee to draft a bill for regulating the practice of medicine. The same committee will present it to the State Legislature and urge its passage. The Society was tendered a reception in the evening by the staff of the Cleveland City Hospital. The Society adjourned to meet at Columbus the second Tuesday in June, 1881.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 27 to July 3, 1880.

Brewer, J. W., Capt. and Asst. Surgeon. His leave of absence, on account of sickness, further extended three months, on surgeon's certificate of disability. S. O. 142, A. G. O. June 28, 1880.

Bartholf, J. H., Capt. and Asst. Surgeon. Having reported at these head quarters., assigned to duty at Fort Coeur d'Alene, Idaho T. S. O. 103, Dept. of the Columbia. June 19, 1880.

Official List of Changes of Stations and Duties of Medical Officers of the Marine Hospital Service of the United States. April 1, 1880, to June 30, 1880.

Bailhache, P. H., Surgeon. Detailed as Chairman of the Board for the Physical Examination of Officers of the Revenue Marine Service—April 28, 1880. Detailed as Chairman of Board for the Physical Examination of Candidates for Appointment as Cadets in the Revenue Marine Service—May 21, 1880. Detailed as Medical Officer Revenue Bark "Chase," during practice cruise—June 1, 1880.

Miller, T. W., Surgeon. Detailed as Chairman Board of Examiners, to convene in New York June 21, 1880—June 4, 1880.

Long, W. H., Surgeon. Granted leave of absence for ten days from April 16, 1880—April 14. 1880. Detailed as member of Board to select a site for a Marine Hospital at Memphis, Tenn—May 12, 1880.

Fessenden, C. S. D., Surgeon. Detailed as member Board of Examiners to convene in New York, June 21, 1880—June 4, 1880. Granted leave of absence for eight days from June 13, 1880—June 9, 1880.

Sawtelle, H. W., Surgeon. Detailed as Recorder of Board to select a site for a Marine Hospital at Memphis, Tenn—May 12, 1880.

Doering, E. J., Surgeon. Detailed as Recorder of Board of Examiners to convene in New York June 21, 1880—June 4, 1880.

Fisher, J. C., Passed Assistant Surgeon. Granted leave of absence for thirty days from May 6, 1880—April 21, 1880. Detailed as Recorder of Board for the Physical Examination of Officers of the Revenue Marine Service—April 28, 1880.

Godfrey, John, Assistant Surgeon. To report to Board of Examiners for examination for promotion—June 4, 1880.

Brown, F. H., Assistant Surgeon. To act as inspector of unserviceable hospital property at Boston, Mass.—April 13, 1880. To report to Board of Examiners for examination for promotion—June 4, 1889. 1880.

Goldsborough, C. B., Assistant Surgeon. Detailed as Recorder of Board for the Physical Examination of Candidates for Appointment as Cadets in the Revenue Marine Service—May 21, 1880.

Keyes, H. M., Assistant Surgeon. To act as inspector of unserviceable hospital property at St. Louis, Mo.—April 13, 1880.

Mead, F. W., Assistant Surgeon. To act as inspector of unserviceable hospital property at San Francisco, Cal.—April 19, 1880.

Porter, F. D., Assistant Surgeon. Granted leave of absence for fourteen days from July 2, 1880—June 29, 1880.

Promotion.

Fisher, J. C., Passed Assistant Surgeon. Promoted to be Passed Assistant Surgeon—April 2, 1880.

Original Communications.

TRACHEOTOMY IN CROUP:

WITH REMARKS ON

THE PATHOLOGY, DIAGNOSIS, PROGNOSIS AND TREATMENT OF THE DISEASE, AND THE CAUSES OF DEATH IN FATAL CASES; WITH A REPORT OF THIRTY-FIVE OPARATIONS.

By JOHN H. RIPLEY, M.D.,

SURGEON TO CHARITY HOSPITAL; PHYSICIAN TO ST. FRANCIS'S HOSPITAL, NEW YORK CITY.

PART III.

CASE XXVI.—R., male, five years old; had been sick and under the care of Dr. S. S. Jones for five days. At the time I was called by Dr. J. to do tracheotomy, the dyspnœa was extreme; the face and lips were blue and cold, and covered with a clammy perspiration; the pupils contracted; the intellect dull. The veins of the neck were engorged, but there was no glandular enlargement, and no cellular infiltration. No membrane in the nares. The tonsils were small and rather pale, the left being partially covered by membrane. The lungs were everywhere tympanitic on percussion, while the conveyed laryngeal sounds obscured all others. Temperature, 102.8°; respiration, 40; pulse, 152. Drs. Jones and C. J. McGuire assisted in the operation, the former giving ether. This anæsthetic, as always happens in my observations in these cases, increased the dyspnœa, and we were compelled to administer it very sparingly. The trachea was opened quickly and easily, and without accident. An abundance of tough, thin membrane was found lining the trachea, which was stripped off and extracted by means of forceps. When the trachea was freed from obstructing substances as much as possible, the tube was inserted and the external wound closed. The relief was only partial, there being still some epigastric and supraclavicular depression on inspiration, and the respirations remaining a little labored. Half an hour after the operation the pulse was 160, and temperature, 102.4°. I did not see the boy again during life, but heard from Dr. Jones that he died at 7 P.M. the same day, nineteen hours after the operation. His respiration and pulse became accelerated, and his temperature rose to 105°. He lapsed into a drowsy, semi-unconscious condition, in which he remained, breathing with labored effort, until he died. Specimens of the tracheal exudative membrane were seen, under the microscope, to be swarming with micrococci. The urine contained bacteria, granular and hyaline casts, and was thirty per cent. albumen. Many of the hyaline casts were exceedingly small, and twisted and doubled upon themselves. The albumen was as white as a washed fleece.

CASE XXVII.—Van W., a fine boy, five and a half years old, complained of sore throat and loss of appetite, Wednesday morning, Nov. 5, 1878. He was sufficiently well, however, to spend the forenoon in visiting with a neighbor's child living on the floor below. In the afternoon he was too ill to sit up, and the parents sent for Dr. C. J. McGuire. The doctor found him feverish and nauseated, and both tonsils were covered with diphtheritic membrane. He at once instituted an orthodox plan of treatment, spraying the throat frequently with a solution of carbolic acid and lime-water, and giving quinine and iron and stimulants internally with regularity. No special change in the symptoms was noticed until Saturday morning (the 8th), when the boy was observed to be a little hoarse. The same morning he had several mucous stools, which were accompanied with tenesmus. During the day the laryngeal symptoms rapidly augmented, with occasional spasmodic attacks of dyspnœa intervening. At 4 o'clock P.M., when I saw him, dyspnœa was continuous and urgent. There was little cyanosis, but complete aphonia and a toneless cough. The usual suprasternal and epigastric recessions occurred during inspiration. The lymphatics of the neck were not enlarged, nor the cellular tissue infiltrated. No membrane could be seen in the anterior nares, although epistaxis of moderate severity had occurred on the same day. The tonsils were congested, and partially covered with a well-defined membrane, as was also the visible portion of the pharynx. The whole chest was tympanitic on percussion; tracheal and large bronchial râles, both moist and dry, obscured the vesicular murmur on auscultation. Pulse, 130; respiration, 24; temperature, 100½°. Dr. McGuire having obtained the assent of the parents to the operation, we proceeded at once to tracheotomize the boy, Dr. Léon having charge of the chloroform. Dr. W. M. McLaury was also present in consultation, at the request of the family. The anæsthetic acted very slowly, but, as usual, modified the distressing dyspnœa almost immediately. The operation was easy, and all but bloodless. No membrane, and comparatively little muco-purulent matter was found in the trachea. Complete relief. Five minutes after the tube was adjusted the pulse had fallen to 90, the respiration remaining at 24. Vesicular breathing could now be heard over all the chest.

November 9th, 10½ A.M.—Breathing easy and noiseless. Little inflammation about the wound. No swelling of the neck. Membrane on both soft palate and uvula. Pulse, 140; respiration, 24; temperature, 101¼°. Urine acid and non-albuminous. Takes nourishment well. No medicine is being given. The atmosphere of the room is kept at a temperature of 80°, and impregnated with steam. 8 P.M.—Pulse, 130; temperature, 103°.

10th, 10 A.M.—Boy bright and playful. Pulse, 128; respiration, 24; temperature, 101.7°. 6 P.M.—temperature, 103°.

11th, 10 A.M.—Has had a bad night. Cough has been very harassing, and he is quite feeble and exhausted. Pulse, 130; temperature, 103°.

6 P.M.—Pulse, 120; temperature, 103°. Water contains a small percentage of albumen.

12th, 10 A.M.—Passed a poor night. Cough persistent, although sedatives were given to control it. Same general bronchitis exists, but no fine râles and no change in percussion sound. Membrane has mostly disappeared from tonsils and soft palate. Pulse, 140; respiration, 30; temperature, 103°.

13th.—Patient looks quite cheerful, and only complains of frequent cough, which is accompanied with an abundance of muco-purulent expectoration. Urine sixty per cent. albumen. Pulse, 140; respiration, 36; temperature, 103°.

14th.—His general appearance is still encouraging, although the other symptoms are less so. The wound is widely gaping, and its edges thick and of an angry-red color, and the odor from it very offensive. The breathing is easy. The urine to-day contains no albumen. Pulse, 140; respiration, 36; temperature, 103½°.

15th.—Still looks well. Wound begins to look healthy. Had a little free tracheal hæmorrhage last night. Complains of his mouth being torn, which, on examination, is found to be the seat of follicular inflammation, and chlorate of potassa is prescribed for it.

The lungs are generally tympanitic on percussion, but auscultation reveals some small areas, especially of the right lung, over which there is absence of all sounds. At the base of the right lung, posteriorly, bronchial breathing can be heard within a circumscribed space. Temperature, 104°; respiration, 50; pulse, 154.

16th.—Is remarkably bright. Expectoration of muco-purulent matter rather profuse. Temperature, 101°; respiration, 48. The condition of the larynx was tested yesterday by removing the tube and placing oiled silk over the tracheal wound. It was found practically impermeable, and the canula was replaced.

17th.—Condition of the patient very unfavorable. He looks anxious and discouraged, and has refused to take food during the night, and his mother says that what little he has attempted to swallow came out through the tube. A teaspoonful of milk, given for the purpose of testing the reliability of this statement, immediately ran out through the tube without exciting the least cough or other irritation. On examining the soft palate, it was seen hanging down in a helpless condition, and apparently lost to sensation. Having removed the tube, a second trial with milk was had, and this time the greater portion passed into the air-passages, but without exciting cough. Pricking the mucous membrane of the trachea—a large surface of which was exposed to view—with the forceps was not felt by the patient. The respirations are superficial, often sobbing, and very rapid—90 per minute. Pulse. 140; temperature, 104°. To be fed only by the rectum.

18th.—Boy still in a desperate condition. He is restless and drowsy by turns, and slowly failing. Medium-sized liquid râles are heard over both lungs, but the percussion note is not materially changed, except over a small area at the apex of the right lung posteriorly. During inspiration there is epigastric and intercostal recession, which is evidently not due to extension of membrane into the bronchi, as there is no other symptom of such a complication. As agreed upon yesterday, the patient has been fed exclusively by the rectum, but the sphincters are becoming relaxed and the enemata are not well retained. Urine still highly albuminous. Pulse, 160; temperature, 105°; respiration, 90, and still often sobbing.

19th.—Patient is deathly pale, but quite bright. The canula was permanently left out yesterday, and the large, ragged, open wound enables one to look into the trachea and examine its interior surface for a distance of an inch with great ease. Several of the rings are very distinct; the mucous membrane is red and swollen, and sensation is nearly lost. Water swallowed escapes partly at the opening, and partly trickles down the trachea into the bronchi without producing irritation. As the sphincters had become so relaxed that enemata were not retained, an attempt was made by Dr. McGuire and myself to pass a small catheter into the stomach, through which to introduce food. Although this was done with the greatest care and gentleness, the instrument had hardly passed the base of the tongue before the boy coughed violently, made an effort to vomit, then the pupils suddenly dilated, the eyeballs rolled upward, the radial pulse disappeared, and respiration ceased. Manipulation and stimulants resuscitated him, but we did not renew the attempt. Dr. McGuire made faithful efforts to prolong life, resorting to hypodermic injections of brandy, and giving small rectal enemeta, but death from exhaustion occurred about midnight, a termination sad and unsatisfactory to all.

Case XXVIII.—P——, male nursling, one year and ten months old; had been sick ten days with intermittent croup symptoms when I first saw him, and had been treated with a solution of chlorate of potassa and muriated tincture of iron during this time. At this visit I observed that his voice was clear and that the laryngeal obstruction was slight. There was no glandular enlargement about the neck, the tonsils were small and pale, and the fauces generally normal. There was no nasal catarrh. A few moist râles were heard on auscultating the lungs. Pulse, 120; respiration, 36; temperature, 101½°. The following day (Nov. 30th) the symptoms were more pronounced and continuous, and in the evening the dyspnœa became severe.

Dec. 1st, 8 a.m.—The condition of the child is now very grave, and the parents are willing to have anything done that will give it a chance. There is still no membrane to be seen, and the fauces are substantially normal. The lungs are generally tympanitic, except a small area over the left posteriorly, which is dull. Over this space no sounds are heard on auscultation, but over the other portions of both lungs vesicular and tracheal sounds are both heard. Pulse, 180; respiration, 46; temperature, 101°.

Drs. Jones and Hawes assisted me in doing tracheotomy. The child was quite fat, although markedly rachitic, and consequently the trachea was deeply situated. Substantially no bleeding occurred except from the tracheal incision, but from this it was quite profuse. Much purulent matter also welled up from the opening and several small pieces of membrane were removed from the trachea. The relief was only partial, respiration remaining rapid and labored, and the epigastric and suprasternal retractions during inspiration occurring, to some extent, after the tube was inserted and everything cleared.

11 p.m.—Pulse, 150; respiration, 60; temperature, 104°. Discharge from the tube profuse; nurses well.

2d, 6 p.m.—Pulse, 160; respiration, 80; temperature, 105°. Respiratory murmur is normal in pitch, but mucous râles are heard all over both lungs. Resonance on percussion is still exaggerated. The discharge through the canula is still profuse.

3d, 10 a.m.—Baby had several convulsions during the night, and its appearance is very unfavorable this morning. The respirations are still frequent and difficult, the pulse rapid, and the temperature remains at about 105°. Has had some diarrhœa and several attacks of vomiting since yesterday. While both tubes were temporarily removed for the purpose of having them cleaned, the mother, who was holding the baby, allowed its neck to get twisted so as to close the opening, when rapid and nearly fatal asphyxia ensued.

4th.—Baby died at 1 a.m. to-day, suffering greatly from dyspnœa to the end. No membrane was present in either the fauces or nasal passages during the entire sickness, neither was there any infiltration of the cellular tissue or glands of the neck. Steam from a croup-kettle was used almost constantly from the first day that I saw the case, and the iron and chlorate of potassa mixture was continued throughout the whole course of the disease.

Case XXIX.—Burke, a remarkably fine boy, two and a half years old, after having had "a cold" for two weeks, developed hoarseness Jan. 4, 1879. Jan. 5th, at 4 a.m., he had an attack of dyspnœa which lasted a few minutes, subsided without treatment, and the boy then fell asleep and remained easy until morning. During the day he was hoarse, but about the room playing as usual. At night, after falling asleep, his mother noticed for the first time that his breathing was noisy. On the following morning (Jan. 6th), before daylight, he had another suffocative attack, which, like the previous one, terminated after a few minutes, without medication. Through the day he was about the house, although the breathing was continuously noisy and the hoarseness more marked. As the evening advanced he began to be restless and fretful, and dyspnœa slowly developed. After midnight he slept little, being kept awake by frequent paroxysms of dyspnœa.

Jan. 7th.—I was sent for at 8 A.M., and, arriving soon afterward, obtained from the mother the foregoing history. The patient was in an extreme condition; the dyspnœa was painful to witness; the face was pallid and covered with a cold sweat, the eyes partly closed and the sclerotic of a bluish color, the extremities cold, and the senses blunted. Both nares were plugged with inspissated mucus. The respirations, carried on through the open mouth, were 40 per minute; the temperature, 97.1°. The lungs were generally tympanitic on percussion, while on auscultation little could be heard except the conveyed sounds from the larynx. No membrane was seen in the throat or nares. The tonsils were large and congested and the neck appeared a little swollen. With the assistance of Drs. Milne and Hawes, I at once tracheotomized the patient. The operation was simple and bloodless. Although the trachea contained a large amount of muco-purulent matter, we did not find any membrane. The relief was complete. The respirations immediately fell to 28 per minute.

10 P.M.—Respiration, 26; pulse, 124; breathing noiseless. Secretion from tube moderate. To have a milk diet and no medicine.

8th, 10 A.M.—The child has passed a fair night, and is looking well. There is a free purulent discharge from both nostrils, and membrane is seen lining the left; still none in the throat. The breathing being harsh, I poured a teaspoonful of warm water into the tube, which excited violent cough, expelling large shreds of membrane, after which the breathing was easy. Pulse, 140; respiration, 38; temperature, 100.8°.

7 P.M.—Breathing harsh, but not sawing. Neck a good deal swollen and face congested. Does not take food well, but appears not to be suffering. A few mucous râles heard on auscultation, otherwise the pulmonary sounds are normal. Pouring water into the tube temporarily relieves the harsh breathing. Pulse, 136; respiration, 38; temperature, 100°. A sister two years older has pharyngo-tonsillar diphtheria.

9th.—Some improvement. Neck less swollen. Child takes food well and appears bright. Pulse, 160; temperature, 100.4°; respiration, 28.

10th, evening.—The prominent symptoms to-day have been great swelling of the neck, harassing cough with profuse, offensive expectoration, drowsiness, high temperature (104°), rapid pulse (160), and frequent respiration (44).

11th, evening.—This morning the symptoms were a little less unfavorable, the boy having passed a comfortable night, and being bright and disposed to play with his toys; but, later in the day, the respirations became harsh, and "sawing," and labored, and signs of exhaustion were apparent. He is now failing rapidly. Temperature, 105°; pulse, 160; respiration, 44.

12th.—Died this morning at seven o'clock. Autopsy eight hours after death. Present, Dr. S. Whitall. The swelling of the neck, which had existed before death, had partly disappeared. On cutting through the soft parts of the neck and chest in the median line, considerable serum oozed from the divided surfaces into the gash. After removing the sternum, a noteworthy amount of emphysema of the cellular tissue of the anterior mediastinum was observed. The lungs were hyperinflated and bloodless, and did not collapse on exposure. A depressed, horizontal, reddish strip was seen in the upper lobe of the right lung, near the fissure. The larynx, trachea, and lungs were then taken out entire. Several large depressed portions of the parenchyma, similar to the one just described, were found in the right lung, particularly in the upper lobes, and a few in the left lung, mostly at the borders; one of considerable extent in the upper lobe—all posterior. By means of a mouth blow-pipe, these parts were easily inflated, so as to be indistinguishable from the adjoining tissue. The lining membrane of the larynx and trachea was slightly congested, not more marked at those points in contact with the canula. A long, tough, tubular piece of membrane was found hanging loosely in the interior of the trachea, attached only to the left vocal cord. On slitting the bronchi, membrane was found lining those of the right lung as far as the sixth division, and those of the left lung as far as the fourth. It was for the most part loosely attached, some pieces lying free in the tubes. Wherever this membrane was found, the mucous membrane of the parts was intensely congested. Very little mucus or purulent matter was found in the smaller ramifications. The spleen was paler than normal. The kidneys were congested, and the left contained two small, recent, superficial infarctions. The liver was apparently healthy. The other organs were not examined.

The sister recovered without croup complications, and without medicine.

CASE XXX.—N——, a puny girl, two years and six weeks old, had been sick three days with croup when I saw her with Dr. Isaac Oppenheimer, Nov. 18, 1879. She had no swelling of the neck or glands. There was membrane on the soft palate and pharynx —none in the nasal passages. She was very drowsy, and rapidly becoming unconscious from carbonic acid poisoning. Her respirations were rapid and labored, and accompanied by the usual signs of laryngeal stenosis. The pulse was feeble; the temperature 101°. The lungs were tympanitic on percussion. With the doctor's assistance I performed tracheotomy at once. The trachea was reached without difficulty and without hemorrhage, but it bled profusely after being divided, and, at the same time, the child partially returned to consciousness, and began to twist itself about on the table. To these complications was added that of an exceedingly poor light, so that we came very near losing the child from suffocation before getting the tube in. After this was accomplished, the breathing became easy and noiseless. The following morning, November 19th, nine hours after the operation, there was some swelling of the neck, but otherwise the symptoms were favorable. Temperature, 101.5°; pulse, 120; respiration, 32.

20th.—Child died about 3 A.M., having suffered much from dyspnœa since midnight.

CASE XXXI.—J. G——, four years and four months old, had been subject to attacks of spasmodic croup since he was a year old. Six weeks ago he had croupy cough and some dyspnœa for several days, apparently due to acute catarrh of the larynx. For the last two weeks he has not felt well, but nothing definite was noticed until about 4 A.M., Monday morning, March 15th, when he awoke with a croupy cough. Dr. Spor was at once sent for and gave an emetic of turpeth mineral. Although this was repeated several times during the day, with emetic effect, the symptoms progressed and dyspnœa supervened.

Tuesday morning (16th) a large piece of membrane was coughed up, and the breathing at once became easy. Two or three hours later, however, it was worse again, and continued to get more and more embarrassed till 3½ P.M., when I was sent for to do tracheotomy. The respirations at this time were very difficult, the half-conscious child rising up in bed and throwing itself into different postures, vainly seeking some relief from the terrible dyspnœa. The cough was dry and toneless, and the voice gone. The face and conjunctivæ were blue, and the extremities cold. The lungs were tympanitic on percussion, and only laryngeal sounds could be heard on auscultation. Temperature, 100°; pulse, 130; respiration, 30. Drs. Milne, Spor, and Judson were present. While we were preparing for the operation, the boy was seized with a fit of coughing so violent that I feared suffocation, and hurried him to the table; but as I placed him upon it all struggling ceased, and I looked into his face to learn the cause. He very quietly leaned over the table and spit out a large tubular piece of membrane three and a half inches long. It was sufficiently explanatory. The operation was, of course, postponed. He continued to breathe freely until 7 o'clock that evening, when the difficulty again returned.

The following morning I was sent for and found him moribund. Dr. Hawes assisted me in a rapid tracheotomy. After the trachea was opened, a large amount of tough membrane was pulled out, which looked like a bunch of tape-worm links. When the tube had been inserted the features rapidly assumed their natural hue, and his mind became clear. But although the breathing was free and the lungs clear, the respirations remained rapid (42). In the evening the respirations were still 42, but labored; pulse, 180; temperature, 103°. He had had several green passages from the mercury, and had vomited a number of times. Great difficulty was met with in getting the stomach to retain any kind of food. He died on the morning of the 18th, the dyspnœa during the last hours of life being almost as great as before the operation.

Case XXXII.—K., a fine girl, four years old, had been sick five days when Dr. Hawes first saw her, April 3, 1876. He found her with pharyngeal diphtheria and a croupy cough. April 4th. She began to suffer from laryngeal obstruction, which had increased to such a degree the following day as to demand tracheotomy. The glands of the neck were somewhat enlarged, but there was no cellular infiltration. The tonsils were congested and partially covered with membrane. Temperature, 102°. Dr. H. gave chloroform, and assisted me in the operation, which was attended with no accident. No membrane was seen during the operation. Complete relief followed, and nothing of special interest occurred until the second day (April 7th), when the temperature suddenly rose from 101° to 103½°, without any ascertainable cause.

April 8th. Temperature still 103°, but no local trouble.

9th. Eruption of measles has appeared, and child doing well.

11th. Eruption fading, and child bright and playful.

12th. Child still doing well. The larynx is tolerably permeable, but it is thought safer to wait till the morrow before permanently removing the tube.

13th. Dr. Hawes was sent for early this morning, because the child couldn't get her breath. He found her dead. The inner canula was completely plugged with inspissated purulent matter. The stupid parents, although cautioned against leaving the child without a watcher, had gone to bed and to sleep, and left it through the entire night without any attendant. They awoke in the morning, saw the child struggling for breath, and sent for the doctor. No other cause of death could be assigned than that of mechanical obstruction of the tube. There were two other cases of uncomplicated diphtheria on the same floor, that occurred a few days later, and both recovered.

Case XXXIII.—M., four years old, had not been feeling well for nearly two weeks, and had had a supposed nasal catarrh during that time. On March 14th he began to cough croupy, and Dr. E. A. Maxwell was called to see him the following day. At that time there was no laryngeal obstruction. On the 16th he was about the same. On the 17th there was some dyspnœa in the morning, but it did not call for surgical treatment. A small white patch was seen, at this time, on the right tonsil. In the evening Dr. M. asked me to see him, as he thought tracheotomy might ultimately be required, although he himself had not seen him for several hours. Much to our astonishment, we found the boy gasping for breath, extremities cold, face pale, except the lips, which were blue, and covered with sweat, and it looked as though we should not have time to operate before death would ensue. Besides, it was a question as to how much of this condition was due to apnœa. The child seemed to be dying quite as much from exhaustion. I hastened for my instruments while Dr. M. made ready the table. Although I was away only about five minutes, the boy was far gone when I returned. The mouth remaining partly open, the lower jaw was, occasionally, at the rate of from four to ten times a minute, jerked downward by a spasmodic inspiration. The eyelids were unclosed, the pupils contracted, and the eyeballs turned upward and insensible. The pulse was still beating feebly and irregularly. The whole body was cold and cadaver-like. Should we attempt the operation? Dr. M. hesitated, and so did I. Both parents were absent, and while we were hurriedly stripping the clothing from the neck, the grandparents savagely warned us not to cut "that dying child." Dr. M. suggested and gave a hypodermic injection of brandy. Dr. M. said, "If that were my child, I would have it operated on, wouldn't you?" I didn't know. At this juncture the father came in, and Dr. Maxwell said, "Your child is dying; will you have us attempt an operation?" Without a moment's hesitation he replied, "Yes." With Dr. Maxwell and Dr. J. J. Delany, who was also present, assisting, I cut rapidly through the superficial tissues, until I came upon several large veins lying directly in the track of the incision; these were held aside by the doctors, and the trachea was opened without further dissection. Meantime the child had been gasping as though every breath were his last. The dilators being introduced, some muco-purulent matter escaped through the tracheal wound with a feeble expiration. By lowering the head and manipulating the abdomen we got an inspiration, then an expiration, and so, by slow degrees, respiration became irregularly established.

The pulse, too, remained irregular for several hours. Dr. M. had meantime given more brandy hypodermically. After the child returned to consciousness, which occurred about three-quarters of an hour after the operation, an incessant cough set in, and continued for a long time, without apparent cause.

18th.—Passed a comfortable night, sleeping several hours. Pulse, 120; respiration, 26; temperature, 101 2°.

5 P.M.—Sleeping. Has been rather restless during the day, and coughed and expectorated a good deal. Pulse, 118; respiration, 26. Takes food well.

19th.—Urine examined by Dr. Maxwell, but neither casts nor albumen found. Child doing well. Had a good night. Temperature, 100¼°; pulse, 116; respiration, 34.

20th.—Patient still improving. No membrane in the fauces, but there is a free muco-purulent discharge from the nose, and the nasal passages are red and swollen and the central portion of the upper lip is the seat of an irritative eczema. The glands of the neck are not swollen. On removing the tube for cleansing, the larynx was found to be slightly permeable. Pulse, 120; temperature, 100.5°; respiration, 26.

21st.—Some bloody expectoration. Temperature, 101°; respiration, 28.

23d.—An attempt was made to-day to permanently remove the tube, but the larynx was not sufficiently patent. Temperature, 100½°.

26th.—A prolonged attempt to leave the tube out was again made to-day by Dr. M. and myself, but severe dyspnœa supervened after closing the opening for a few seconds.

April 2d.—Prof. Louis Elsberg examined the larynx to day and found the aryteno-epiglottidean folds and the superior vocal cords so swollen as to form a double cushion on either side, nearly meeting in the median line. There was no membrane seen. He recommended the using of some astringent spray, and Dr. Maxwell subsequently applied a solution of tannic acid, glycerine, and water.

April 11th.—Tube removed to-day. Some spasmodic dyspnœa occurred immediately after taking it out, but this soon subsided, and before we left, the wound had so closed that respiration was carried on almost entirely through the larynx.

5 P.M.—Boy suddenly developed a temperature of 103½° without premonition. Dr. M. and myself finding no local lesion to account for the fever, suspected malaria. This was rendered the more probable, as other members of the family had recently suffered from it. Quinine, and, subsequently, Warburg's tincture was given, with good result. The fever was entirely under control by the 16th, and the patient discharged cured on the 18th. No medicines were given to this boy after tracheotomy was done, except a sedative cough mixture during the first twenty-four hours. He pretty constantly inhaled simple steam from a croup-kettle during the first few days, and took stimulants and nourishment freely. An older sister was attacked with diphtheria while he was sick and made a good recovery.

CASE XXXIV.—D., twenty-five months old, although a markedly rachitic boy, had always been fat and healthy, except that he sometimes suffered from attacks of malaria. A week ago the parents noticed that he had a severe coryza, and at the same time he lost his appetite and became peevish. Last evening (April 8, 1880), about 5 o'clock, croupy cough set in so steadily that the father consulted Dr. Malcolm McLean, at the latter's office. Dr. McL., not being well himself, sent a prescription for an emetic of squills and ipecac, which, having been given, afforded temporary relief. About 3 A.M. the following morning, however, the cough got worse, the breathing became difficult, and Dr. McL. was sent for. On his arrival, recognizing the case as one of true croup, he ordered an emetic of turpeth mineral, and sprayed the throat with lime water. After the action of the emetic, which resulted in the expulsion of some shreds of membrane, the breathing was easier. At 11 A.M., when I saw him, the cough was metallic and the breathing slightly noisy, so as to be heard when sitting close to the child. There was slight laryngeal obstruction. The child was drowsy from having been awake during the night. The glands at the angle of the jaw were little enlarged. The voice was pretty clear. Both tonsils were covered with a grayish, gauze-like membrane. No nasal discharge and no membrane in the passages. The lungs were clear. The spleen was enlarged. Pulse, 136; temperature, 102.5°; respiration, 36.

As the child had had previous attacks of malaria, twenty grains of quinine, in divided doses, were ordered to be given during the succeeding twenty-four hours. Also poultices to the neck, and spray and steam inhalations, and brandy and milk by the stomach.

5 P.M.—The boy has slept nearly all day, but the breathing has become more noisy, and the usual signs of laryngeal obstruction are present. The membrane has nearly disappeared from the tonsils. With the mirror we were enabled to see a small patch on the aryteno-epiglottidean fold, and that the interior of the larynx and the epiglottis were much congested, the latter so swollen as to resemble the uvula.

10th, 2.30 A.M.—Stenosis has progressed to such a degree as to imperatively demand an operation. Child very restless; flushed face; loud, stridulous breathing, which can be heard in the hall below, and hacking cough. The voice is not lost, but husky. Lungs tympanitic, but no vesicular murmur can be heard, only laryngeal whistling. Pulse irregular; temperature, 99°; respiration, 48.

Dr. McLean being too ill to be present at the operation, Dr. Hawes assisted me, giving chloroform. The hemorrhage was trifling. Quite a large strip of limp membrane came into the upper angle of the wound after the trachea was opened, but I did not succeed in getting it. No membrane lined the trachea. Five minutes after the tube was in, the respirations were easy, but 45 per minute; temperature, 100°. Not much cough.

10.30 A.M.—Boy restless and does not take food well. Breathes easily. Pulse, 120; respiration, 48; temperature, 101°. Membrane again on both tonsils, and a small strip on the right anterior pillar.

9.30 P.M.—Asleep, breathing easily, but respirations 60 per minute. Very little cough, and scanty discharge from tube. Lungs clear. No nasal discharge. Less membrane on tonsils. Does not retain quinine well, which is the only medicine given. Steam from a croup-kettle has been constantly used from the first.

11th, 11 A.M.—During the night the temperature rose to 102½°, and the respirations to 60. There has also been some dyspnœa, which cleaning the tube mostly relieves. The membrane on the tonsils is now about a line thick, and of a yellowish-white color. Wound looks well and there is no swelling of the neck. More discharge from the tube than yesterday. Breathing a little harsh, but lungs resonant. His general appearance is good but he does not take food well. Temperature, 101¼°; respiration, 46; pulse, 124. To have six grains of quinine at one dose.

6 P.M.—The quinine was retained. Although the boy has been playful and has taken nourishment well since my last visit, his breathing has been noisy and rapid. After cleaning the tubes and giving a bronchial emetic of warm lime-water the breathing became noiseless, and remained so during the hour that I remained with him. He also got bright and playful, and waved a cheerful good-bye when I left. Temperature, 102°; respiration, 58; pulse, 124. A small specimen of urine which I examined contained ten per cent. of albumen.

12th.—The baby has had a pretty fair night and is looking as well as he did yesterday. Temperature, 102.5°; respiration, 38.

6 P.M.—Child in a hopeless condition. Respiration sawing and labored, countenance dusky, commencing drowsiness. Some areas of dulness on percussion. Tracheal and moist and dry bronchial râles heard on auscultation. Temperature, 103.5°; respiration, 60. After all other means of relief had failed, we gave him small doses of morphine, which proved a most satisfactory remedy in controlling the harassing cough, and in inducing quiet and peaceful sleep. He died the following morning at 4 o'clock.

Post-mortem examination twelve hours after death, the body, meantime, having been on ice. Present, Drs. McLean and Hawes. After opening the thoracic cavity, it was noticed that the anterior portion of the left lung in view was distended and bloodless. The right was partially collapsed and of a rose color. Transverse markings of interlobular emphysema were noticed in this lung, some a line in width and nearly an inch long, and others of less extent, mostly in the lower lobes. A few were observed in the other lung also. The lungs, trachea, and larynx were now removed entire. On inspection, the upper and middle lobes of the right lung were of a bluish-red color generally, some parts being of a brighter red. These lobes were firm to the feel and did not crepitate. The lower lobe was greatly distended with air and comparatively bloodless. The whole of the left lung was hyper-inflated and pale. A blow-pipe being introduced through the tracheal opening, the upper and middle lobes of the right lung were inflated perfectly, and without very much force being required. The larynx and trachea were then slit down posteriorly, when the internal face of the epiglottis was found covered by a thick, milk-white membrane, the interior of the larynx congested, and membrane extending from the vocal cords, to which it was rather firmly attached, the entire length of the trachea, and forming nearly a complete lining of that organ. At some points it had become detached, at others it was loosely adherent, while at others, again, it was so firmly adherent that it was difficult to peel it off. The same was true of the bronchi of the right lung to about the fifth division generally. In the left lung the membrane was not so uniformly present in the smaller tubes, but extended equally far in some directions. The mucous membrane of those parts invaded by membrane was much congested, but very little muco-purulent matter was found in the lungs. The thymus gland was large. The spleen measured 3½ × 2½ inches, and was very hard. The kidneys were slightly congested. The liver appeared normal. The pericardium contained about two drachms of clear serum. Nothing abnormal was discovered with the heart. The other organs were not examined.

CASE XXXV.—K., a German boy, four and one-half years old, played in a puddle of water in the street on the third inst., and in the evening was hoarse, and had a profuse nasal discharge. The following morning the hoarseness was much worse, and a doctor was called, who said the boy had diphtheritic croup, and ordered emetics of turpeth mineral. During the succeeding twenty-four hours he took three emetic powders, which produced free vomiting, but gave no relief. At 10.30 A.M., June 5th, I saw him, Drs. Robert Millbank and Clements being also present. He was a thin, delicate-looking boy, and, his parents said, was much subject to bronchitis, and had once had pneumonia. He had also suffered much from earache, and once or twice had had purulent discharges from the right ear. At the time I saw him he had two suppurating onychias on one hand and one on the other—the first two being of traumatic origin. There was a purulent discharge issuing from both nares, the parts were red and swollen, and a small, grayish patch was seen in the left nostril which looked like membrane. Its pultaceous quality, however, ascertained by removing it, made its nature doubtful. The cervical glands were not enlarged. The fauces were normal. By depressing the tongue the most of the epiglottis could be seen, which was red and swollen. No membrane seen. The dyspnœa was marked, and on stripping the chest and abdomen, each inspiration was seen to be accompanied by well-marked supra-clavicular, intercostal and epigastric retraction. The deformed pigeon-breast proved antecedent rachitis. Inspiration and expiration were alike obstructed, and accompanied with stridor. The voice was hoarse, and the cough dry and ringing. Percussion over the left lung was rather dull; over the right tympanitic. The true respiratory murmur was lost, and the expiratory sound prolonged. Moist râles were heard at the base of both lungs. Pulse, 148; respiration, 26; temperature, 101.5°. As there was yet little cyanosis, I proposed to wait a couple of hours before resorting to tracheotomy which had already been consented to by the parents. But, after watching the boy for a few minutes, I was satisfied that the stenosis was rapidly increasing, and decided to return in an hour. This proved to be a wise decision, as, at the expiration of the hour, the breathing was very difficult, and the lips blue. Drs. Milne and A. M. Vance assisted me in operating, Dr. M. giving chloroform. No accident happened. No membrane was found in the trachea, but careful search was not made. Immediately after the operation the breathing became easy and noiseless. Pulse, 120; respiration, 28; temperature, 101°. Vesicular breathing over both lungs. A few mucous and sonorous râles.

5 P.M.—Breathing a little labored, but lungs clear. Patient very thirsty. Pulse, 140; respiration, 30; temperature, 103.2°.

10 P.M.—Pulse, 128; respiration, 40; temperature, 103.4° (Milne).

June 6th, 11.30 A.M.—Patient was quite thirsty during the night, but otherwise comfortable. Had several loose passages, probably from the mercurial emetics which he had previously taken. Discharges from tube profuse, also increased nasal discharge. Some small flakes of membrane seen in the nostrils, and what looks like a small deposit on the left tonsil. Some swelling around the wound. Boy still thirsty but looking well. Pulse, 116; respiration 42; temperature, 101.4°. Urine contains five per cent. of albumen.

4.30 P.M.—More membrane on tonsil. Pulse, 116;

respiration, 36; temperature, 102.4°. Dry and moist râles in left lung.

7.10 A.M.—Sleep was disturbed last night by frequent coughing. Less nasal discharge. Parts about the wound swollen and hard. Membrane gone from tonsil. Looks well. Pulse, 114; respiration, 38; temperature, 102°. Removing the tubes in order to clean them excited cough, and a very large quantity of thick, tough membrane was expelled, two pieces of which each measured one inch and a half in length and a quarter of an inch in width. No air could be got through the larynx, in spite of this expulsion of membrane, thus showing that it came from below.

4 P.M.—Boy has lost his cheerfulness, and is now inclined to sleep. Breathing is not harsh, lungs resonant, mucous and sibilant râles heard on auscultation. Thirst continues. Discharge from tube scanty. Pulse, 124; respiration, 52; temperature, 103.6°.

8.10 A.M.—The boy is no worse this morning. He slept pretty well during the night. Takes nourishment well. Still some nasal discharge. Some membrane on the wound and a great deal daily expelled through the tube. Pulse, 138; temperature, 102.2°; respiration, 52.

4 P.M.—Several small, tubular pieces of membrane expectorated since morning. None to be seen in the fauces. Urine albuminous, and contains also a few epithelial casts. Boy about the room.

10 P.M.—Pulse, 108; temperature, 101.4°; respiration, 46 (taken by Dr. Milne).

9th.—Much improved. Passed a good night. More membrane expelled. The whole wound and contiguous abraded surfaces covered with soft, grayish membrane. Larynx still occluded. Pulse, 80; temperature, 100.5°; respiration, 48. Drs. Milne and Millbank present.

5 30 P.M.—Still about the room, looking well. Profuse expectoration of bloody, purulent matter. Wound looks angry. Pulse, 120; temperature, 102.2°; respiration, 30.

10th, 10 A.M.—Has a good appetite. No membrane expelled since yesterday, that on the wound loosening. As the breathing is pretty easily carried on through the larynx, I remove the tube for the day. Pulse, 106; temperature, 100.5°; respiration, 52. The breathing is shallow.

6.30 P.M.—Father says the boy has been playing about the room most of the afternoon. There is diminished respiratory murmur over the left apex, which is temporarily improved by forcible coughing. Skin hot and dry. Temperature, 103°; respiration, 54; pulse, 114. Dr. Milne, who is attending the case with me, is to see the boy at 10 P.M., and, if the temperature has fallen at that hour, quinine is to be given.

June 11th, 10 A.M.—Dr. M. found the temperature 101.2°, and ordered three grains of quinine to be given every three hours. Boy looks better. Tissues about the wound puckering. No membrane has yet appeared in the fauces. The mucous membrane of the trachea, as seen through the wound, looks red and swollen. The tube, which was replaced last evening, is to-day again left out, probably permanently. A pad of oakum is placed over the wound. Quinine to be continued. Pulse, 98; temperature, 101°; respiration, 42.

6 P.M.—A small area of erysipelatous redness over the right temporal region. Pulse, 110; temperature, 101.5°; respiration, 48.

12th, 10 A.M.—Erysipelas has extended, and now involves the lower part of the right ear, and the affected parts are elevated above the adjoining skin. The wound still shows no sign of granulating. Boy looks bright. No recent change in the pulmonary signs. Pulse, 120; respiration, 80; temperature, 104°.

5.30 P.M.—Boy catching flies. Has been taking five drops of tincture of iron every hour since morning. Quinine discontinued Pulse, 112; respiration, 48; temperature, 102.2°.

13th, 10 A.M.—Erysipelas now involves the scalp of the parietal region, but is fading. Expectoration profuse. Over the lower two-thirds of the left lung, posteriorly, the respiration is broncho-vesicular. Temperature, 103.2°; respiration, 80; pulse, 114.

6 P.M.—Bronchial breathing over nearly the whole of the left lung. Erysipelas unchanged. Boy still appears to suffer very little, sits up in the bed, and plays most of the time. Temperature, 104°; respiration, 80; pulse, 120. Oil-silk jacket and febrifuge mixture ordered.

14th, 10 A.M.—Expectoration of purulent matter has been profuse since yesterday. Erysipelas fading out. Liquid râles heard all over both lungs, especially over the left. Very little bronchial breathing to-day. Late last evening the temperature was 101.4°, this morning it is 102.4°.

6.30 P.M.—Temperature, 103°; respiration, 52; pulse, 104. Urine still albuminous. Since yesterday morning he has taken 36 grains of quinine on the supposition that there might be malaria complicating the other affections.

15th, 10 A.M.—Boy about the same. Wound of a dirty yellowish color—cadaveric. Pulse, 106; temperature, 103°; respiration, 88.

6 P.M.—Lungs full of liquid râles; bronchial breathing again marked over left lung, but disappears to a great extent after coughing and free expectoration. Respiratory paralysis evidently explains some of these anomalous and changeable symptoms. Pulse, 98; temperature, 102.8°; respiration, 44.

16th, 10 A.M.—Appearance is very bad. At two o'clock this morning he was attacked with a sharp pain in the left chest, just above the nipple, and has suffered with it ever since, being unable to sleep or even to take a deep inspiration. A distinct, moist, friction-sound, is heard over the point indicated, while bronchial breathing is very distinct over the rest of the lung anteriorly and posteriorly. Percussion is generally dull over the whole lung. Exaggerated breathing with liquid râles is heard over the right lung. Temperature, 104; respiration, 102; pulse, 140. I directed the parents to envelop the entire chest with a hot flaxseed-meal poultice, and renew it every six hours.

4.30 P.M.—Poultices were applied properly, and have given much relief. Erysipelas, which had nearly disappeared, is bright again. For the first time the boy does not care to sit up. Pulse, 120; respiration, 74; temperature, 103.5.°

17th.—Much the same, but weaker, at 11 A.M. Pulse, 140; respiration 74; temperature, 103°.

10 P.M.—Temperature, 102.3°; pulse, 124; respiration, 80.

18th, 10 A.M.—The patient has been very restless and feeble during the night, and has had several attacks of vomiting. He is now unable to sit up longer than a minute or two at a time. His countenance is of a leaden hue, and the capillary circulation very poor. The pulse is very feeble and remitting, beating at 60; temperature, 102°; respiration, 70. All medicines to be discontinued, and brandy, in drachm doses, to be given every hour, and the boy to be kept in a reclining position.

6 P.M.—Pulse, 140; respiration, 60. The pulse is regular, and stronger than in the morning. Bronchial breathing is still present over the left lung, but a few moist, fine râles are also heard.

19th, 10 A.M.—Boy looks cheerful again. Had a good night. Only a small area of erysipelas remaining over the frontal region. The tracheal wound has a pinkish appearance to-day for the first. Bronchial breathing still present over left lung. Respiration, 50; temperature, 102°; pulse, 140.

6 P.M.—Wound covered with creamy pus. As the brandy now nauseates him, it is to be given less frequently. Poultices to be removed, as the lung appears to be resolving, and the temperature is low. Pulse, 120; respiration, 44; temperature, 101.8°. Urine still contains a few epithelial casts, but no albumen.

20th.—Patient now has some appetite, and slept well during the night, still he does not look as well as he did yesterday. Tongue is much coated, and skin is hot, but I have no thermometer. Pulse, 120; respiration, 50.

4 P.M.—Pulse, 144; temperature, 104°; respiration, 64. No new physical signs. What next? 10 P.M.—Temperature, 104.5°.

21st.—The boy looks pale and feeble, but otherwise his condition is better than yesterday. The wound looks well, and is beginning to granulate and contract. Fine subcrepitant râles are heard all over the left lung. Pulse, 140; temperature, 102°; respiration, 44.

6 P.M.—About the same. Pulse, 120; respiration, 42; temperature, 101.8°. 10 P.M.—Pulse, 120; respiration, 40; temperature, 101°.

July 9th.—This boy died June 26th—three weeks after the operation. From the date of the above report (June 21st) until death, the more prominent symptoms were: high, remitting temperature, not controlled by quinine; physical signs of beginning lung infiltration; diarrhœa; rapid emaciation. In the absence of a *post-mortem* examination, which was curtly refused, I think the immediate cause of death was acute tuberculosis, and have so tabulated the case.

The subjoined table exhibits the results in the preceding cases:

AGES.	No. of Males.	No. of Females.	No. of Recoveries.	No. of Deaths.
Under one year	..	1	..	1
Between one and two years	4	..	..	4
" two and three years	3	3	1	5
" three and five years	10	6	4	12
" five and seven years	6	2	3	5
	23	12	8	27

CAUSES OF DEATH.

Bronchial croup,	14
Uræmia,	3
Toxæmia,	2
Cardiac paralysis,	2
Accidental plugging of tube,	2
Uræmia and respir. paralysis,	1
Pneumonia,	1
Erysipelas and bronchial croup,	1
Acute tuberculosis,	1

(To be continued.)

TWO CASES OF TREPHINING—RECOVERY.

By WEBB J. KELLY, M.D.,
GALION, OHIO.

WHILE attending my first course of lectures, I distinctly remember visiting the Academy of Medicine one evening, and sitting two hours and listening to a discussion on whether it was best to operate before or after the patient had passed into a comatose condition, in fractures of the skull. Our professor of surgery arose and said: "Gentlemen, if you are going to operate, do so at once." It struck me very forcibly that he was right, and as it has been my good fortune to operate twice successfully, once when the patient was in a comatose condition, and once when he was not, I will give the profession the benefit of my experience.

CASE I.—Charles Yager, seven years of age; American; rather delicate; farmer's son. June 11, 1877, was called, in consultation with Drs. Reed and Bennett, of Iberia, to see this boy. He had been playing in the yard, and, as was afterward ascertained, struck a horse's heels with his hat, when the horse kicked, striking him in the head. He was found by his mother in a comatose condition, which state he was still in when I saw him, four hours afterward. Examination revealed a compound comminuted fracture of the right parietal, at the junction of its articulation with the left parietal and the occipital, with decided compression. I advised an operation, and, after warning the parents of the danger connected with it, proceeded to operate. Chloroform was administered, and, although our light was miserable, we were very successful in elevating the detached fragments without rupture of the membranes. Two of the pieces taken away were quite large, one being two inches long by one and a quarter wide, the other being about two-thirds the size of the former. The patient recovered consciousness immediately after the pressure was removed from the brain, and was able to recognize his parents. The wound was left open, and the patient placed in a darkened room in a position to favor drainage. Controlled the circulation with veratrum viride and aconite, and, as he showed extreme signs of anæmia, ordered ten-drop doses of tinct. ferri chlor. An "ice-bag" was applied to his head and kept there until he was out of danger. In seven weeks from the time of injury he walked into my office, feeling well, and to-day he is attending school, and is apparently as bright as if he had never been injured. The aperture caused by the loss of bone is gradually filling in, and is covered with a thick scalp. It seems to me that, in this case, the operation saved the patient's life.

CASE II.—Arthur Nasor; residence Ontario, O.; aged 23 years; farmer; good habits; strong and healthy. While crossing the railroad track he was struck by a freight engine, which was running about twenty-five miles an hour. When the train stopped he was found hanging to the rods above the pilot. When taken down he was able to walk back to the caboose, and when they arrived here, he walked to my office, a distance of eight blocks. Inspection showed a large wound over the front part of the head, from which arterial blood was flowing pretty freely. An examination revealed a compound, impacted fracture of the frontal bone a little to the left of the median line, and at the junction of the articulation of the frontal and left parietal bones. This examination was about 2 P.M., and it was my wish to operate immediately, but, owing to the absence of his friends, I was delayed until 6.30 P.M. He was already beginning to pass into a comatose condition; pulse very slow and full, showing signs of congestion. He was etherized; the wound enlarged and a button removed from in front of the fracture. It was then with the greatest difficulty that I could remove the impacted fragment, part of it having gone through the membranes into the brain-substance itself. The removal of the bone was followed by such an extravagant gush of blood that death seemed inevitable. The patient lay unconscious some ten or fifteen minutes, and then opened his eyes and was able to recognize friends. The bone which was removed was exactly the size of a silver dollar, and the shape of the bolt which drove it into his brain. The wound was dressed with carbolized water, and the patient made to lie in a position to favor drainage. His room was darkened, and the ice-bag applied to his head. What shall I say of the treatment? This and nothing more! The ice was kept to his head night and day, and whenever there was the slightest symptom of congestion he was given a good full dose of Rochelle salts. Not another drop of medicine was given him, and to-day, ten weeks from the day of injury, he is in as apparent good health as he ever was.

Both these patients recovered without a single bad symptom, and when I say I do not agree with Ashhurst when he makes the assertion: "Hence, in impacted fractures, though compound and depressed, I would not advise an operation even if symptoms of compression were present," I think there are others who will uphold me. There are a few points in the after-treatment of trephining cases to which I should like to refer.

1st. Never, under any circumstances, close the wound. If it is small and you have removed any fragments of bone, better enlarge rather than close it. Leave a large opening for drainage, and *keep* the patient in a position to favor that drainage.

2d. Ice to the head. I think in both the above cases the patients' lives were saved by the cold applications. If possible, have it a dry cold. It retards and oftentimes completely wards off the inflammation.

3d. Absolute rest. And lastly, don't, just because they are in danger of having convulsions, coma, etc., dose your patients with prophylactics. Let them alone with the ice to their head and a good free drainage, and there will be better results from the operation.

June 7, 1880.

NECROSIS OF POPLITEAL PLATE OF FEMUR.

SUPPURATION OF KNEE-JOINT—PASSAGE OF DRAINAGE-TUBE THROUGH THE JOINT—RECOVERY WITH MOTION OF JOINT.

By PROF. GEO. E. POST, M.D.,

BEIRUT MEDICAL COLLEGE.

MARIAM, aged 17, Wadi Shahrûr, Mt. Lebanon. Ten months since, there appeared an inflammatory swelling of the lower part of the thigh, involving the knee-joint, accompanied with great pain. The girl says that the abscess opened of itself on the inner and lower aspect of the knee-joint, and was afterward punctured on the outer and upper aspect of the joint, opposite the exterior border of the popliteal space. She says that much matter came out. On the 15th of November, 1879, she came to St. John's Hospital with a swollen and stiff knee, and sinuses in the positions mentioned above. The joint was tender on pressure, and a probe passed from one sinus to the other traversed the joint, touching dead bone in its passage.

Soon after her entrance the two sinuses were enlarged by incisions sufficiently to allow of the introduction of the finger and sequestrum forceps. The finger, introduced into the inner sinus, passed freely into the joint, and came in contact with the posterior surface of the patella. Two large fragments of bone, constituting the whole of the popliteal plate of the femur, with a part of the cancellated stricture adhering, were removed through the exterior sinus. Two quarter-inch drainage-tubes were then passed from sinus to sinus, traversing the joint, and, during the subsequent treatment, injected several times a day with carbolic solution, one to twenty. The wounds were dressed with lint wet with the same solution. The constitutional symptoms were slight and the discharge moderate. Her condition, which was one of great feebleness at her entry, improved steadily under the use of citrate of iron and quinine. Several months after the operation she had a slight attack of cutaneous erysipelas in the affected limb. Six months from the commencement of treatment she was discharged cured, with the sinuses quite healed, and able to flex the joint fifteen degrees, walking with a slight halt, and in a perfect state of general health. There was no pain or tenderness about the joint, and little swelling.

I have long believed that the chief advantage of the elaborate antiseptic system of Lister consists in drainage and cleanliness. I am accustomed to results as good as those ensuing from the more troublesome procedure, with relief from the fatiguing details, which become impossibilities in circumstances such as those which are inherent in practice in Syria.

Pyæmia and septicæmia are so rare in our hospital, where the essentials of antisepticism (not Listerism) are observed, that our students often finish their studies without having seen a case. In fact, we have had but half a dozen in twice as many years.

DR. JAMES McCREA, of Philadelphia, committed suicide by cutting his throat with a razor, on June 21st. Dr. McCrea was an active member of the City Board of Health and highly esteemed as a physician and a man. He had for some time, however, acted peculiarly, and had been urging that the sessions of the Health Board should be in secret.

PHLEGMASIA ALBA DOLENS FOLLOWING OVARIOTOMY.—G. C. Smythe, M.D., of Greencastle, Ind., writes: "Under the head of 'Medical Items and News,' in the number of your journal of April 10, 1880, you make mention of a case of ovariotomy, published in the *British Medical Journal* by Dr. Alfred L. Galabin, which was followed, upon the fifteenth day, by phlegmasia dolens, in which he claims that this is the first case of the kind ever reported. On the ninth day of February, 1880, I removed an ovarian tumor from Mrs. Julia Hostetter, at Terre Haute, Ind., which was followed upon the twelfth day by phlegmasia alba dolens, from which the patient made a good recovery. The details of this case are published in the *American Practitioner* for May, 1880. I call attention to this case as being the second one of the kind reported."

Reports of Hospitals.

BUFFALO GENERAL HOSPITAL, BUFFALO, N. Y.

Indolent Ulcers and their Surgical Treatment —Bromide of Ethyl.

(Extract from a Clinical Lecture delivered at the Buffalo General Hospital.)

By CHARLES C. F. GAY, M.D.,

ATTENDING SURGEON.

Gentlemen:—No better proof of the intractability to medical treatment of indolent or chronic ulcers could be afforded than by the several patients occupying beds in the surgical wards of this hospital at the present time. There are under treatment ulcers upon one or both lower extremities, varying in duration from three months to twenty years. Lotions and unguents have failed to cure them.

The duration of these ulcers would be regarded as a reproach to surgery did I not believe that patients refuse to yield full assent to such surgical measures of relief as are deemed proper and wise.

In the majority of cases you will find these chronic ulcers associated with varices. Varix holds the relation to them as cause and effect; if we expect to cure them we must treat the veins, and in this hospital varicose veins have been treated for the past few years almost exclusively—and I may add successfully—by eschars produced by the potassa cum calce.

It is found, if the ulcers be not too intractable, that they heal simultaneously with the healing of the eschars.

But these ulcers are not always dependent upon diseased veins; therefore other methods of relief must be practised. Plastic operations have long been in vogue, but we cannot always induce patients to accept the alternative of an operation that appears to them at all formidable. Skin-grafting has been tried with varying results; but I am sorry to be obliged to say, that in my own experience it has been more fruitful of failures than of successes.

John Gay, Esq., Surgeon to the Great Northern Hospital, London, England, published, in 1855, a monograph entitled, "A Memoir on Indolent Ulcers and their Surgical Treatment," which I have read with pleasure and, I trust, profit. The author's treatment consists mainly of incisions, and since so good an opportunity has recently been afforded us, this method has been put somewhat to the test.

This man, J. W——, æt. 45 years, had an ulcer of fourteen years' duration upon his leg, one inch by three inches in diameter, beginning near and above the internal malleolus, and running over the leg anteriorly, which is well represented by the accompanying figure.

The ulcer has been two or three times closed within the fourteen years, during warm weather. The ulcer is associated with varices. Three weeks ago to-day I applied the potassa cum calce over the veins, causing three eschars which have not yet healed. At the same time I made a curved incision, three inches in length and three-fourths of an inch distant from the posterior border of the ulcer, cutting through the indurated integument and subcutaneous fascia.

The principle involved in the treatment is the same as that of the plastic operation, since the incised wound gapes open, and the isthmus of skin is partially drawn over the ulcer. The ulcer of this patient's leg is now closed up in its entire extent, and the question arises as to how much of the cure is attributable to the three eschars, and how much to the incision. So rapid a cure of so large an ulcer could not fairly be placed to the credit of the eschars.

Other cases are, at present, under treatment by incisions alone, and thus far are progressing well, and promise the best results.

Incisions, when practicable, ought to be made upon either side of the ulcer, and of proper distance from the border. In one case under treatment, the incisions were made too near the border of the ulcer, and the strip or isthmus of integument, which was only one-fourth of an inch in width, sloughed away. The incision should be made farther from the ulcer's border. Three-fourths of an inch distant is probably too far away, since the incised wound would be less likely to gape. Incision, probably half an inch from the border, would be about right.

BROMIDE OF ETHYL.

In the case of J. W. the new anæsthetic was administered. It required eleven minutes to bring the patient under its influence, and nine drachms were used. Its odor was very disagreeable, its effect was evanescent. Two drachms had previously put the house physician asleep, and during its administration to the patient, the doctor—who appears to be unusually susceptible to the effects of anæsthetics—came near falling asleep.

Another patient, a very strong man, just as he was coming under the influence of the same anæsthetic, became excited, violent, and unmanageable, sprang from the table, and escaped to his bed.

Progress of Medical Science.

The Guinea Worm.—A very large number of attacks from the parasitic disease known as Guinea worm (*Dracunculus Medinensis*) has lately been officially reported by Mr. Dutt, assistant surgeon in Chouda, Central Provinces of India (*The Brit. Med. Journal*, March 27, 1880.) 178 cases came under Mr. Dutt's notice from one village alone. At the date of the report, 137 of these had been cured, one had died, and 40 remained under treatment. All those who obtained water from a certain muddy well suffered more or less from the disease, while those that were not allowed to touch the well were almost totally exempt from it. According to Mr. Dutt, the worms gained access to the bodies from the habit men had of going to the well and dipping their hands and feet in it, thus allowing the zoösperms of the infected water to come in contac twith the skin. Thus the hands and feet are the parts attacked by the worm, and these were the members affected in all the patients but one, in whom the worm appeared in the abdomen. The reporter adds that in England there need be no fear of this formidable parasite; but in the tropics its ravages are well known and greatly dreaded. As to the treatment, the time-honored method of extraction is still the one most successfully employed at the present day. This is done by winding the exposed or protruded end of the parasite round a small stick of ivory, bone, or wood, or even round a portion of adhesive-plaster, cardboard, or stout paper. Rupture of the worm during extraction must be carefully avoided. From this statement of the mode of infection it will be seen, that the author has taken no cognizance of Cobbold's views regarding this subject. Cobbold, it will be remembered, attributed to Fedschenko the discovery of the true source of the guinea-worm. On page 223 of his able treatise on parasites, we find the following: "Fedschenko showed that the embryos of dracunculi, after quitting the human host, succeed in effecting an entry into the bodies of entomostracous crustaceans belonging to the genus cyclops. Within these intermediary bearers, after twelve hours' sojourn, the embryos undergo a change of skin, attended with subsequent growth. Here they remain to complete their larval development, which takes place within a period of five weeks. At length, as perfected larvæ, they are, together with their crustacean hosts, transmitted to the stomach of the ultimate or human bearer. It is probable that sexual maturity is next acquired within the human stomach, copulation following. After this, the females migrate to the situations in which they are found beneath the skin of the human bearer, whilst the males perish and pass out with the fæces." Hence, it appears that infection takes place by direct transference of infested entomostraca to the stomach by water used as drink. From this it follows that the filtering of water before use would suffice to secure immunity from attacks of the guinea-worm disease.

Treatment of Constitutional Syphilis by Sulphate of Copper.—Drs. Martin and Oberlin gave a brief report on this subject at a late meeting of the Paris Academy of Medicine. The authors treated 50 patients, who showed various manifestations of syphilis, by the copper sulphate. The results were quite satisfactory, the 50 patients all being cured. A comparison of this method was made with the ordinary mercury methods, and it was found that the copper salt proved more efficacious and required less time for its beneficial action than did the mercury salts. The copper was also well borne by most patients; in only one case it produced initial vomiting, followed, however, by permanent tolerance of the drug. In a case of very grave syphilis, when mercury had proved useless, the administration of copper effected a rapid and complete cure. In a few patients, the gums became affected, a greenish tint appearing at their free border. But this cupric gingivitis yielded more rapidly than the analogous mercurial affection ordinarily does. Actual sponginess of the gums was not observed. The salt was exhibited by the mouth in doses of gr. $\frac{1}{16}$—gr. $\frac{1}{6}$ per day. An aqueous solution was employed. External application was also made by adding 5 drachms of the salt to a full bath.—*Gaz. méd. de Paris*, April 10, 1880.

The Obstetric Treatment of the Perineum.—In the above paper Dr. Garrigues, of this city, gives a description of the perineum and external organs of generation, at the same time combating many errors that prevail in reference to the anatomy of the parts. In speaking of lacerations, he says that ergot should not be given until after expulsion of the placenta, as it hastens the delivery before there is sufficient dilatation of the obstetric canal, and may result in laceration. He also advises, as a means of lessening the chances of this accident occurring, that the rectum shall be thoroughly evacuated by an enema of warm water. He advocates the support of the perineum, but not until the presenting part has commenced to dilate the vulvar orifice. In the intervals between the pains a kind of enucleation may be performed by passing the index and middle finger of the left hand into the rectum and pressing against the forehead of the child, thus aiding in the expulsion of the fœtus. When the shoulders are passing through the external orifice, he claims that if the posterior one be pushed backward, or the anterior pulled forward by means of the index finger hooked in the axillæ, perineal laceration may, in many instances, be avoided, as he has many times examined the perineum before delivery of the body, and found no laceration, whereas it existed afterward. When the vaginal orifice is too small, he recommends episiotomy, which can be performed by cutting the constrictor vaginæ muscles on each side. All these methods of procedure, according to the circumstances existing in each case, are recommended by Garrigues, to avoid, if possible, a perineal laceration. If a laceration takes place which is slight, he employs serres-fines, one to three being used. They are applied as follows: the lips of the wound are raised up by means of the thumb and index finger of the left hand, and the serrefines applied with the right, commencing with that portion of the laceration near the anus. They are allowed to remain about four days, when they are removed. He speaks very highly of them, because of the ease with which they may be applied, and also on account of the small amount of pain occasioned by their application. In extensive lacerations, sutures must be applied, and a description of different methods of suturing is given. —*Reprint from Am. Journ. of Obstet.*, April, 1880.

Ethyl Bromide.—Dr. Lawrence Wolff, of Philadelphia, has recently published a paper on bromide of ethyl as an anæsthetic, which, in view of the recent discussions as to its properties, possesses more than an ordinary degree of interest. In describing the manner of preparing the drug, mention is made of a brown acrid liquid remaining after the bromide is distilled off, and which possesses an unpleasant and pungent odor. Twenty drops of this latter liquid was administered to a rabbit, causing symptoms of irritation of the gastro-intestinal tract, and death in eighteen hours. At the post-mortem, the brain was found to be congested, the abdominal viscera were also congested and irritated, and the odor of the liquid was given off. On the other hand, 30 grains of the pure bromide of ethyl had been given to the same animal, previous to this, and no unpleasant symptoms were produced. Several experiments were made with similar results. In one instance in which the rabbit died while under the influence of the pure bromide of ethyl, the brain was found to be in an anæmic condition, and the odor of the ethyl could not be detected in the organs. W. is inclined to believe that death in Dr. Sims's case was due to the presence of the heavy distillate above mentioned; in support of this view he says that, ethyl bromide being a volatile substance, its odor would not probably be detected forty-one hours after administering it. He does not believe that it is unstable in its composition, as some say, he having failed to separate the bromine from the ethyl, after repeated attempts. The following conclusions are arrived at: rabbits, which are with difficulty anæsthetized, can be ethylized with success and without danger to life. When employed hypodermically the ethyl causes an increase in the number of respirations. No greater toxic effects are produced on the system by its use than would result from the administration of ether or alcohol, so that danger from this source need not be apprehended. Also, that while it cannot be positively stated that pure ethyl bromide is *per se* an absolutely safe anæsthetic, yet it is as safe as ether, and more so than chloroform. He recommends that the drug should have a place in the new pharmacopœia.—*Reprint from American Journ. of Pharmacy*, May, 1880.

Caries of the Ankle in Children.—The Results of Expectant Treatment from a Study of Thirty Cases.—Dr. V. P. Gibney has tabulated the results of expectant treatment in thirty cases of the above disease. In fourteen cases the disease manifested itself previous to four years of age; in eleven instances the patients were from four to nine years old, and in five from nine to thirteen years. In fourteen patients the lower epiphyses of the tibia and fibula, as well as some of the bones of the tarsus, were involved; in ten cases the tarsus alone was implicated; in four, the tibia and fibula only; and in the remaining two, the os calcis was involved. As to suppuration, in nineteen cases it was quite profuse, in six moderate, and in five no pus was formed. The length of treatment averaged one year and three months, the shortest being less than six months, the longest nearly three years. The duration of the disease was from one to six years. Several cases were examined at varying intervals after the cure, and in all, the joint affected was found to remain in a state of health. Of those cases, and there were five, in which shortening of the limb was found to exist, it was not more than one inch. The shortening of the foot was as follows: half an inch in sixteen cases, less than one inch in four, none in three instances, and in seven it was not ascertained. In two-thirds of the cases there was no lameness, in seven it was slight, and only in one case was the lameness at all marked. In five cases the mobility of the joint was perfectly restored; in the other patients there was a slight impediment to perfectly free motion in certain directions; in two of these the tibio-tarsal joint was anchylosed, but this was compensated by an increased degree of mobility at the medio-tarsal articulation. The conclusions drawn from the paper are as follows: If a conservative course of treatment be adopted, the joint affected can be saved. Excision of a joint, in children, is rarely ever justifiable. No advantages are offered by partial excision, or passing tents through the joint, more than can be obtained by the expectant plan of treatment. By this method of treatment, although there may be some anchylosis and deformity, the limb is rendered more serviceable than in any other way.—*Reprint from Am. Journ. of Obstet.*, April, 1880.

The Influence of Varicocele on the Nutrition of the Testicle.—In a recent clinical lecture. Dr. J. C. O. Will, of Aberdeen, presented a case of varicocele, which had resulted from an injury to the left testicle. The varicocele was of great size, and the nature of the swelling could be diagnosed without even the slightest manipulation of the parts. The testicle of the affected side was so wasted that it had entirely lost the form usually presented by that organ, and it seemed to be a mere appendage to the diseased veins to which it was attached. After giving some of the opinions advanced by eminent surgeons, Dr. Will said that in all the cases he had met with, where the varicocele had been large, the history had pointed to a traumatic origin. Concerning the therapy, he believed, that in the great majority of cases, the best mode of treatment was the establishment of proper sexual relations. Yet he felt satisfied that cases did frequently occur, for whose relief radical treatment was absolutely called for. The extent of the disease must form our guide in this matter. Operative interference, after palliative treatment had been given a fair and prolonged trial, was recommended under the following conditions: 1, if the varicocele be very large, or increasing; 2, if the testicle be atrophied; 3, if acute pain be complained of; 4, if the patient be disqualified from entering the public service; 5, if the stability of his mental faculties be endangered. This last condition was not a mere fanciful one, and was met with often enough. But he would not advise an operation unless there be real and well-marked mischief. The mere desire of a patient, who suffers from slight varicocele, for an operation should not influence the surgeon in this respect. Greater latitude in the direction of operative interference might be allowed in those cases, where the thoughts of the patient are concentrated—often to the exclusion of all others—upon the supposed serious malady from which he is suffering, than in those where the patients are willing to accept the physician's assurance that slight varicocele is an affection of but little significance or importance.

Thrombosis Arteriæ Coronariæ Cordei.—Dr. A. Wislizenus, of St. Louis, reports the following case of obliteration of one coronary artery of the heart: The patient, a German, thirty-four years old, of strong constitution, had had, a year before, an attack of acute rheumatism, and a second attack one month ago. From the latter he was just recovering, his pulse during convalescence beating at the rate of eighty in a minute. Suddenly, while sitting in a rocking chair, he was seized with collapse. The extremities became cold, the pulse sank to forty per minute, and was feeble but regular. He had no pain, and his intellect remained clear. Examination of the chest showed no sign of exudation either in the heart, lungs, or pleuræ, nor any organic cardiac disease. The pulse gradually fell to eight in a minute. Examination of the heart in this condition revealed first a feeble, but still distinct systole and diastole lasting one second, then a clonic cardiac spasm, with a vibrating sound lasting five seconds, then a quiet pause of two seconds, and so on in the same regular manner. In the absence of all other organic defects, one of the attending physicians, Dr. Hammer, by the method of exclusion, came to the conclusion that such a sudden collapse and gradual sinking could only be explained by a sudden obliteration of one of the coronary arteries of the heart. The patient died on the third day. The post-mortem examination was allowed only on condition that the heart alone should be examined. In the pericardium about a spoonful of serum was found; in the ventricles, quantities of fibrinous coagula; the endocardium and valves were normal, the muscles anæmic. On examining the semilunar valves of the aorta, which were themselves sound, a large thrombus of fibrinous clots and excrescences was discovered in the right sinus Valsalvæ, that extended to the outlet of the coronary artery and completely obliterated it. This complete obliteration in all probability occurred very suddenly.

Tubercular Tumors of the Mammary Gland.—M. Prichet recently observed a case of tubercular mammary tumor, at the *Hôtel-Dieu* (*Gaz. des hôp.*, May 13, 1880), the patient being a woman, aged fifty years. On admission the left mamma was enormously swollen; the appearance of the skin was masked by former applications of tincture of iodine.

It presented numerous small elevations, which had been treated with irritant lotions for the past eighteen months. There was eczema below the breast on both sides. Beneath the integument of the mamma a hard, elastic tumor was felt. It exhibited two principal prominences, which were situated at the external portion of the gland, and comprised about one-half of the whole organ. The inflammatory phenomena rendered the nature of the tumor quite obscure. Antiphlogistic remedies were employed to put the breast into a condition favorable for diagnosis. Several abscesses were opened, and creamy pus escaped. After the inflammation had subsided, the appearances were found to have become considerably altered. The external portion of the left mamma was now the seat of a firm, elastic tumor, about as large as a turkey's egg, and showing three chief lobules, two of which had been incised. Pressure here no longer gave rise to the escape of pus, but was followed by the appearance of a yellowish, somewhat viscid substance, resembling thick lymph. "The tumor is not painful, and presents about the same size it had two years ago. The patient believes it is rather smaller, and this certainly speaks against the cancerous nature of the tumor. The manifest tendency to cicatrization likewise militates against the correctness of such a diagnosis." Syphiloma of the mamma was likewise excluded, on account of the stability of the tumor during anti-syphilitic treatment. Adenoma mammæ was also an improbable diagnosis, and so, finally, caseous tubercular tumor was the only remaining possibility. It was only the rarity of such affections, which justified some hesitation in regard to the acceptability of this diagnosis. In this particular case, however, the strumous condition of the patient, the existing chloro-anæmia, and the physical chest-symptoms, clearly pointed to a disseminated tuberculosis. Mammary tumors of this kind, M. Richet added, resembled tubercular orchitis and cheesy swellings of the epididymis. Removal of the breast was always necessary, and having been performed in this case, a subsequent examination verified the clinical diagnosis.

Rapid Lithotrity with Evacuation.—Dr. E. L. Keyes gives the results of the experience of himself and Dr. Van Buren with this operation. From the numerous cases that are being reported in the medical journals, and from the increased sales of lithotrites by surgical instrument makers, he concludes that the operation is becoming widely adopted, and has already become a part of general surgery. Dr. Keyes believes that this is as it should be, and that litholapaxy is destined to supplant slow lithotrity and lithotomy to a large extent. Litholapaxy is an operation which can be undertaken by the general surgeon, but never until he has performed lithotrity at least once or twice, and thus accustomed himself to the feeling of a lithotrite in a sensitive bladder.

Dr. Keyes bases his opinions on the new operation upon nineteen cases performed in males past the middle age. The following points are discussed:

Injuries to the bladder and urethra.—Injury to the bladder is not of great importance if the bladder is left empty afterward; injury to the urethra, especially its prostatic portion, is much more serious.

Origin of the operation.—The credit of originating the operation is given unconditionally to Professor Bigelow. The tolerance of the bladder to long sittings, and the benefits secured by an early removal of fragments had been understood, but the operation of litholapaxy itself is exclusively the property of Bigelow.

The record of cases operated on by Dr. Keyes shows a mortality of one. In this case the patient was in a bad condition, being sixty-seven years old, and having pyelitis already. The oldest patient was seventy-three, the youngest forty-six. The stones were generally phosphatic. The greatest length of time at any one sitting was eighty-five minutes, the shortest ten minutes. The average yield was four and one-half grains of detritus to the minute; a higher average will undoubtedly be obtained in future. In most cases large tubes were not employed, Nos. 13 and 16 (English) being the usual size.

The complications of the operation were unimportant. Retention of urine occurred in one case, chill and fever in another. There was always a slight fever, and the urine was bloody, as a rule, for several days.

There are no contraindications to the operation, except hopeless maladies of any kind, distortions of the urethra preventing the introduction of instruments, and possibly a very large and hard stone.

Preparation of the patient for operation is very important. If the patient has atony, and his urethra is accustomed to the use of the catheter, nothing more is absolutely necessary, although it is better to put him to bed for a few days, and wash out the bladder with borax and water. In other cases the occasional passage of a sound is advantageous; the free use of some bland diuretic is advisable in all cases. Ten grains of quinine two hours before the operation, and ten minims of Magendie's solution just before the operation, may be given. At the time of the operation the meatus and anterior strictures may be cut, but not deep strictures.

In the operations the Thompson washing-bottle and a Keyes' lithotrite were used.

In the after-treatment, aside from meeting symptoms as they arise, washing out the bladder with a saturated solution of borax is to be recommended. Borax is preferable to carbolic acid, being as antiseptic and less irritating.

Statistics show that up to the present time one hundred and seven cases have been operated on, with six deaths, making a mortality of about five per cent.

The limit of time of a single sitting is placed by Thompson as thirty minutes; Keyes, however, lays down no rule except that the operation should be done as rapidly as possible.—*American Journal of Medical Sciences*, April, 1880.

◆

Northwestern Dispensary, N. Y.—The twenty-seventh annual report of this dispensary states that 22,469 patients have been cared for in 1879, or 400 less than in the previous year. Of this number, 4,016 were treated at their homes by the visiting physicians. In those classes where there is a decrease, it has been slight, except in the vaccination department, which shows a decrease of thirty per cent. There has been an increase in the classes of surgery, skin, and eye and ear of twenty-six, forty-three, and sixty-five per cent. respectively; the list of new patients in the last service being 917. A Diet Kitchen Association, under the control of ladies, is attached to the institution, to which the visiting physicians refer as of great aid in the care of sick children and consumptives. Donations to the amount of $2,613.50 have been made during the year.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

MEDICAL LEGISLATION DURING THE PAST SEASON.

We have referred at various times, during the past winter, to the medical legislation undertaken or accomplished in the State and National Assemblies. A partial review of this may be of value now, as showing the especial objects which our profession is seeking from the lawmakers, and also the measure of influence which medical councils have in securing such laws.

There are two directions in which the energies of medical men and medical organizations have been especially directed. These are the establishment of State Boards of Health and the regulation of the practice of medicine. Concerning the former, there is but one opinion as to its desirability, and that is a favorable one. We have already shown how the belief in the value of these organizations has found expression practically in the action of State Legislatures. Health boards have been created in Maryland, New York, and Iowa. In addition to this, the laws in regard to the Health Boards of California, Mississippi, Kentucky, and New Jersey, have been amended, so that the powers and duties of those boards, especially of the latter three, are now much enlarged. In Ohio alone, a bill to establish a health board failed. The profession is aroused upon the matter, however, and such failure will not be likely to occur another winter.

Laws regulating the practice of medicine concern us even more nearly than those establishing health boards. That the profession is beginning to feel very strongly upon the subject is shown by the earnest attention paid to it at nearly all the State medical societies, whose annual meetings have recently been held. From these meetings there appears to be a substantial agreement that the practice of medicine should be regulated by law, in some way. But the exact mode is not so easily settled. There are many complications, arising partly from our defective system of medical education, and partly from the fact that the different medical schools must be recognized, no matter how low their scientific standing or how futile their therapeutic methods. It is a fact, also, that such laws as are desired must be framed with great care and carried out with unwearying vigor and watchfulness; otherwise they fail, as they have done in Kansas.

During the past winter, bills to regulate the practice of medicine have been introduced into the legislatures of Massachusetts, Maryland, Iowa, and New York. They failed in all these States except the last. We can say of these failures, however, as of that in Ohio, that they are only temporary. Our medical organizations have for the most part taken up the matter energetically, and we believe that proper laws will, before a great while, be enacted.

There were attempts last winter, in Maryland, Virginia, and Kentucky, to secure a law giving a certain precedence to doctors' bills in the settlement of estates, or the disposition of the property of the defunct. These all failed; in Kentucky, in particular, the bill not only received no favor at all, but was defeated. The idea of enacting such a law is a good one; that is to say, it is founded on a sense of justice to medical men. There is no reason why the undertaker and the landlord should be paid in full, and the doctor be left without a fee. There is, however, a deeply-rooted feeling that the doctor's services establish not so much a monetary as an emotional claim, which can be discharged to a large extent by explosive expressions of gratitude; and until this feeling is much changed we doubt the possibility of bills for medical services ever rising above the legal status of bills for coffins or bills for board.

The subject of the relation between druggists and physicians has been much discussed of late, but it has only reached one legislature, that of California. Here an unsuccessful attempt was made to prohibit druggists from giving or physicians from receiving a percentage on prescriptions. We have before referred to the inadvisability of attempting to regulate by law a matter which is immoral only when viewed in a professional and not in a business light.

The State of Iowa has enacted a law regulating the practice of pharmacy. The same legislature refused to regulate the practice of medicine. Their new law is an experiment, and appears like a piece of superfluous legislation. Whether it succeeds or not, other States will profit by the experience.

There have been a number of minor matters before our legislatures, of more or less medical interest. These need only be briefly alluded to. The establishment of a night medical service in this city is a measure which will be watched with much interest, since its success will lead undoubtedly to its wide adoption. The same may be said of the law enacted in Connecticut, compelling railroad employees to be examined for color-blindness. There has been, also, some legislation in regard to pleuro-pneumonia, and to the adulterations of food, which we need not particularize.

The work of Congress has been conspicuously barren in results. The bill to establish a Veterinary Bureau failed; so also did that to place the Marine Hospital Service on a higher basis. The National Board of Health received about $100,000, which is not so much as it wanted, though more than it at first seemed likely to get. The Board will be enabled to carry on its work, but must give up some of its special quarantine stations. An appropriation for printing the catalogue of the Medical Library was made. The other scientific results of the recent session of Congress must be represented chiefly by an appropriation of $7,500, to investigate the value of sorghum as a sugar-producer; and a somewhat larger sum to enable the country to show plaster-casts of fishes at Berlin.

Our State legislatures have, however, done some very good work. Doctors are learning better every year how to get their influence recognized and their bills made laws. There is strength in organization; this has become appreciated. And there is a surprising efficacy in the knowing just how to manage things, as was shown by the able manner in which the bill to establish our State Board of Health was gotten through the legislature last winter.

As regards political methods, doctors may be classed with the children of light, but they are beginning to learn some of the wisdom which is so potent with the children of darkness.

THE POSITION OF THE DENTIST.

CONSIDERABLE feeling has been excited in England over the views which the *Lancet* has expressed in regard to the professional position of the dentist. That conservative journal has taken the ground that the dentists, or those who hold, as the bulk of them do, a diploma in dental surgery, are not to be considered in any sense members of the medical profession. Furthermore, it is not permitted them to contribute to the columns of the *Lancet*, because they are professionally inferior. This last prohibition was brought about through an invitation which the editor issued to his readers to furnish information upon the subject of the extraction of teeth and putting them back in the jaw. None but medical men, or dentists who had a medical degree or license, were allowed to contribute to the discussion. It appears that the dentists of England have, of late years, become a body of considerable scientific attainments and prominence. A good many write themselves "surgeons practising dentistry," and are rather above the old-fashioned dissyllable which their fathers used. There has been much effort made to show that dentistry is no longer a mechanical trade, but a branch of medical science, which deserves to rank with other specialties, like ophthalmology or dermatology. Although these efforts to elevate the art deserve every encouragement, it will be acknowledged, we think, by most, that the *Lancet* is right in refusing, as yet, to recognize dentistry as a medical specialty. No class of persons has any right to claim membership in the medical profession, or to presume to form any branch of it, until such persons are doctors of medicine themselves. It is in this respect that dentists differ from oculists and gynecologists, etc. The latter must first get their regular medical diplomas. If dentists would also first get such a degree, they could justly claim every equality with other members of the profession; and such equality is, indeed, already granted everywhere. It is a fact, however, that the demand for highly educated dentists is not yet great enough to justify more than a small proportion of that profession from getting a medical degree. The degree of dental surgeon which so many do get in this country insures a good educational training and a fair amount of medical knowledge. It is making the dental profession one which is much more respected, and which is doing excellent scientific work. This diploma in dental surgery, however, is not enough to entitle him to the claim of practising a surgical specialty.

The attempt, in England, to elevate the standard of dentists by law has led to a rather curious result, if we may believe the statements of Dr. Archibald H. Jacob, of Dublin, in the *Medical Press*. He asserts that by this law, recently enacted, 4,806 persons became admitted to the profession of dentistry, of whom only 531 possessed any recognized medical, surgical, or dental qualification. The law gives them the privilege of calling themselves surgeon-dentists, and puts them, officially and legally, on a par with surgeons. Considerable dissatisfaction has naturally been felt.

◆

REPORT OF ST. JOHN'S GUILD FOR THE YEARS 1877, 1878, and 1879.—The St. John's Guild has had the misfortune to get under a cloud during the past few years. There are said to have been "irregularities," and there certainly has been bad taste in some of its methods of doing business. There can be no question, however, that in spite of this the Guild has done very good work. In the summer of 1879 it took 27,818 children and mothers out on its excursions. An excellent feature of its work is a sewing department. The Guild is trying now to establish a seaside nursery at Staten Island, where, in the language of the report, "the lives of infants may be saved by giving them nature's wonderful remedy for cholera infantum—the ozone of sea-air." This same "ozone of sea-air" has about as much to do with checking diarrhœa as the "dollar of our daddies." Nevertheless the nursery will be a most useful institution, and it is to be hoped that it will be well supported.

Reviews and Notices of Books.

Observations on Fatty Heart, comprising Remarks on the Morbid Anatomy, Symptoms and Diagnosis, Prognosis, Etiology, and Treatment. By Henry Kennedy, A.B., M.B. Dublin: Farmin & Co. London: Baillière, Tyndall & Cox. 1880.

The first opinion that one forms of this book is that the author is a very poor writer and a rather wild pathologist. But with further study these facts grow less prominent and we have to admit that Dr. Kennedy has worked over his subject long and earnestly, both at the bedside and in the dead-house. He writes, therefore, from extensive knowledge, and has really made a contribution to medicine which has a good deal of value as well as originality.

We believe it worth while, therefore, to present some of the facts and conclusions which the author has given. The task is not an easy one, for the author has an exasperating tortuosity of style and delirium in arrangement. We do our best, however.

The book, in the first place, should be entitled "On Fatty Degeneration" rather than Fatty Heart, for the former is the subject which is really discussed. Beginning with *morbid anatomy*, the subject is divided into that of Fatty Growth and that of Fatty Degeneration: most of the observations bear upon the latter division. When fatty degeneration begins to affect the system it is to be found in numerous organs. Thus it appears in the arteries, where its sequence is bony deposit; in the nerves, cord, and brain, where a not unfrequent sequence is serous infiltration, a condition sometimes found in general paresis of the insane; there is sometimes a fatty degeneration of the ganglionic centres and of certain nerves. It is suggested that such affection of the cardiac ganglia may be one of the causes of fatty heart; the author has also found fatty degeneration of the pneumogastric in connection with fatty hearts. There is a rather preposterous suggestion that the cause of the slow pulse in fatty heart may be a degeneration of the right pneumogastric, which Masoin has shown to have the greater inhibitory power. Fatty degeneration may be observed in the voluntary muscles of those who cease to exercise and of the young who are given to drink. Fatty degeneration of the diaphragm is a frequent accompaniment to that of the heart; the intercostal muscles may also be thus affected. Ogle's statistics show that in 100 cases of fatty liver there are 68 cases of fatty heart. With reference more particularly to the heart, the author speaks of the coexistence often of fatty growth and fatty degeneration. He insists strongly that *in fatty disease of the heart valvular disease is exceptional*, there being such complication only in about one case out of five. When there is valvular disease, it is generally with fatty growth, and is confined to the aortic valves. These are thickened and pulpy from deposit of fat, but are smooth and water-tight. Fatty growth on the heart rarely occurs without a deposit of fat elsewhere. Fatty degeneration is a disease of lean persons. It is most marked in the left ventricle where the ruptures occur, and begins on the internal surface, as a rule. The arcus senilis accompanies this sometimes, but is not a sure index of it. There is generally a bony deposit in three places—the coronary arteries, the arch of the aorta, and the cartilages of the sternum. The latter is an important fact, and may often help in diagnosis.

The author discourses at great length upon the *symptoms*. From out of his discursiveness there may be gathered the conclusion that *fatty growth* can be positively diagnosed when, 1st, there is a large, full pulse, beating at the natural standard of frequency; 2d, when percussion shows the area of cardiac dulness is increased, this being due to the deposit of fat; 3d, by the possible presence of a soft murmur over the aortic orifice, occupying the first sound of the heart only; 4th, by the condition of the individual as to his being fat, or becoming so.

As symptoms of *fatty degeneration* of the heart (the whole system being generally involved at the same time), there are found a large number of nervous phenomena due often to serous effusion. The best known of these is the pseudo-apoplectic attacks. This is absolutely pathognomonic, but it does not occur in a large proportion of cases. The patient is generally older than when fatty growth occurs. He is apt to be thin also; indeed, loss of flesh is sometimes a symptom. The arcus senilis, flabby muscles, diminished power of keeping up the animal heat, muscular weakness, pains close to the diaphragm or over the heart, dyspnœa, puerile respiration, are all symptoms indicating fatty degeneration. The pulse in this condition is slow in a certain proportion of cases—about 1 in 10; it may be intermittent; it has also the quality known as "sedateness." Physical examination will show the impulse and heart-sounds to be weak; occasionally the latter have a distinctly musical character. The heart sounds have also sometimes a character of "smallness" which is very noticeable.

The author is confident that the disease can almost always be recognized, and the two forms of fatty affection be distinguished.

In some general remarks, which conclude the author's description of the symptoms, he makes the suggestion that pernicious anæmia and general paralysis of the insane have sometimes fatty degeneration as part of their pathology.

The treatment which is recommended for fatty growth is that for obesity in general: exercise with heavy clothing, a limited, dry diet (and the author considers milk more dangerous than alcohol), fucus vesiculosus and potash in certain classes of cases, and setons, form the basis of the therapeutic measures to be carried out. For fatty degeneration, a careful temperate life, tonics, with alcohol for emergencies, are indicated.

We have given in the above an abstract of only part of the book, which contains much that is instructive and suggestive, together with some things that are very crude.

Lessons in Gynecology. By William Goodell, A.M., M.D., Professor of Clinical Gynecology in the University of Pennsylvania, etc. With ninety-two illustrations. 8vo, pp. 454. Philadelphia: D. G. Brinton. 1880.

This book, its author informs us, is "not a treatise upon the diseases of women, but mainly the outcome of clinical and of didactic lectures delivered to the advanced students of the Medical Department of the University of Pennsylvania." In whatever light Dr. Goodell chooses to regard his collected lectures, the profession will doubtless find in them the able and scholarly digest of matured opinions on many subjects of interest and importance in his department.

How very readable a volume we have before us is conclusively shown by the call for a second edition, scarcely six months after the publication of the first.

The work is divided into thirty-three lessons, treating successively of gynecological instruments, the modes of examination and the various disorders of the sexual apparatus. Lesson IV. contains a good *exposé* of the vesical troubles so frequently complained of by women who have borne children. The following lesson gives a rather inadequate account of fistulæ of the female genital organs. After some remarks about closure of the vulva for incurable vesico-vaginal fistula, tumors of the vulva, and other affections of these parts, we come to Lessons VIII. and IX., which are devoted to a consideration of the causes, the prevention, and the cure of laceration of the female perineum. Metritis and endometritis are next taken up, and then come several lessons on the various uterine versions and flexions. In Lesson XV., on the use of the closed lever-pessary and of the intra-uterine stem-pessary, Dr. Goodell states that, "take it all in all, the very best pessary yet devised is Hodge's closed lever-pessary, or such a modification of it as Smith's." To this we cannot assent. No one pessary is or can be "the very best" for every given case.

Prolapse of the womb and laceration of the cervix uteri are next discussed, and then follows a rather short but interesting chapter on uterine cancer. In speaking of Freund's method of extirpation of the womb, the author admits the small percentage of recoveries thus far reported, but he adds that "in so cruel and so hopeless a disease it is large enough to justify further trial of the operation."

Vegetations of the endometrium, polypus, and fibroid tumors form the headings of the three following lessons, and then comes a good chapter on ovaritis and prolapse of the ovaries. Other ovarian diseases are then described, and their usual treatment explained. Lesson XXX. clearly shows the intimate relation existing between certain nervous disorders, so frequently the subject of complaint on the part of our American women, and ordinary, sometimes very slight, diseases of the womb. The book closes with chapters devoted to practical matters, such as faulty closet accommodations and the like. The final lesson is devoted to a bold and intelligent statement of the author's views concerning "the sexual relations as causes of uterine disorders."

On the whole the book contains but little to criticize. If we should have preferred fewer scriptural quotations, others might, with perhaps equal propriety, have wished for more; if we find more questions suggested than solved, this is probably only owing to the author's judicious abstention from useless theorizings, and pseudo-explanations. There have been, and still are, certain vexed matters in gynecology, as well as in other sciences, which seem to recede from, rather than approach satisfactory solution, as additional light is thrown on them by advancing experience. Dr. Goodell seems to have recognized this fact, for where science fails to give us the key to certain unexplained and, perhaps, inexplicable phenomena, he does not seek to supply the missing link by the substitution of personal dogmas.

Common Mind-Troubles, and the Secret of a Clear Head. By J. Mortimer Granville, M.D., M.R.C.S., etc. Edited, with Additions, by an American Physician. Philadelphia: D. G. Brinton, 1880.

The author of this little work, we are told by the nameless American editor, "has devoted more attention than most physicians engaged in the specialty of treating deranged intellect to the earliest and faintest symptoms of that terrible malady." Notwithstanding this praiseworthy surplus of attention, Dr. Granville has not, in our opinion, succeeded in presenting to the general reading public a very desirable book. Some unsuspecting mortal of perhaps somewhat eccentric habit of mind or body will, by reading this volume, suddenly discover that his peculiarities of character are early symptoms of a deranged intellect. By thus having his attention forcibly drawn to some utterly harmless personal peculiarity or confirmed habit, he may at length convince himself and others that his mind is in truth deranged. This will not be reassuring, and may prove positively injurious.

We can feel no sympathy with this and similar premature attempts to popularize subjects which stand in such need of more extended and more exact knowledge.

Brain and Mind; or, Mental Science Considered in Accordance with the Principles of Phrenology, and in Relation to Modern Physiology. By Henry S. Drayton, A.M., and James McNeill. Illustrated. 12mo, pp. 334. New York: S. R. Wells & Co.

This work upon phrenology, a pseudo-science which has already passed its grand climacteric, contains much that will address itself to the popular fancy. It is a curious example of Aristotelian reasoning, abounding in rules with many exceptions, and yet written withal in a fascinating style.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 20, 1880.

Fordyce Barker, M.D., LL.D., President, in the Chair.

Dr. Frank H. Hamilton read a paper entitled

A NEW REMEDY FOR CHRONIC CYSTITIS, AND OTHER CHRONIC INFLAMMATIONS.

In August, 1875, Dr. Hamilton was consulted by a lawyer, Judge G., aged 63, for chronic cystitis. The patient had always been a man of temperate habits, except that he used tobacco excessively. He had, however, for a long time worked extremely hard, neglecting the care of his health. About a year before consulting Dr. H., he had been obliged to give up his work on account of the cystitis, and to devote himself to its cure. He had tried a large number of remedies, but with no success. When seen by Dr. Hamilton, he was emaciated and weak. He could scarcely travel at all. He had to pass his water every half hour or hour. At times he suffered intense pain in the bladder. His appetite and digestion were impaired. An examination showed that he had no stone nor enlarged prostate. His urine contained about 25 per cent. of pus, with renal casts.

He was advised to drink flaxseed tea for its aperient and diuretic effect; to take a hot bath every night, and to ride horseback every day. The flaxseed tea was soon given up, as it disturbed his digestion; the hot baths were soon discontinued also. The plan of horseback riding was at first protested against, as the slightest jolting always gave him great pain. It was, however, undertaken. At first the horse was walked very slowly. At the end of a month he was able to ride two miles; at the end of two months the pus had disappeared from the urine, and in six months he was completely well.

Dr. Hamilton said that this was not the only case which he had seen benefited by the same kind of treatment. A physician of New York City had suffered for a long time from chronic cystitis and pyelitis. Medicines and rest had been faithfully tried, but with no effect. He finally began drinking flaxseed tea and riding horseback. He was completely cured, but ascribed some of the good to the flaxseed tea.

Another physician with whom he was acquainted had suffered in the same way, and had been cured in much the same manner, though in this case the patient had driven in a carriage more than he had ridden.

Dr. Hamilton was aware that the value of constitutional treatment in chronic cystitis was well-known and had been insisted upon by others. He did not think, however, that the particular form now recommended had been ever before brought forward. From some remarks made by Dr. Gouley he had inferred that that gentleman was aware of its importance, but it was not mentioned in his book.

Dr. Hamilton wished to lay stress on his belief that constitutional causes lay at the bottom of a great many chronic inflammatory conditions, and a knowledge and remembrance of this fact were necessary to successful treatment. Anæmia and disturbances of digestion were often a part of this constitutional vice. Such diseases as chronic conjunctivitis, otitis, bronchitis, pharyngitis, laryngitis, urethritis, and arthritis are examples of inflammations dependent generally on constitutional causes. Not one of these can, as a rule, be cured by local measures. Even a chronic congestion and displacement of the uterus may be relieved by riding in the saddle and attention to general hygienic measures alone.

Dr. Hamilton would not depreciate the value of other forms of exercise and recreation, but he was inclined to consider horseback riding as the best.

In reply to an inquiry whether horseback riding was contraindicated in cystitis with enlarged prostate, he stated that he believed it was.

The paper being open for discussion,

Dr. E. C. Harwood said that, as a personal sufferer from cystitis, he could corroborate Dr. Hamilton's views as to the value of constitutional treatment. Several years ago he was working very hard, and had neglected proper exercise. His urine was examined at that time by a friend, who told him he could not live six months. His treatment, though not exactly like that suggested by Dr. Hamilton, consisted in attention to hygiene chiefly. He ate very freely of grapes, drank a glass of sweet cider every day, and took cod-liver oil. This resulted in a cure. He believed in the horse and saddle, and thought that the opinions in regard to their value, expressed by Dr. Hamilton, were correct.

THE REPORT OF DELEGATES TO THE NATIONAL PHARMACEUTICAL CONVENTION

was read by Dr. Laurence Johnson, and accepted. [A full account of the convention has appeared in a previous number of the Record.]

A paper was then read by Dr. Wm. A. Thomson on

THE PROPHYLACTIC USE OF COD-LIVER OIL.

Dr. Thomson began by remarking that next in importance to discovering a new remedy was the ascertainment of how it acted. This latter, indeed, may sometimes be of more importance, for such discovery may add to our knowledge of the pathology of the disease. Thus, if we knew how mercury relieved syphilis, we should know what syphilis is. There is one class of remedies, however, whose action we are beginning to learn something about. These form the class known as restoratives. They are really only a kind of food, and as starvation is a very common condition, especially after febrile conditions, such kind of medicines is very often needed.

The way in which iron acts may be studied as an illustration of the rest. Iron enters into the composition of the red blood-corpuscles, and is essential to their functional activity. These corpuscles carry oxygen through the system. Iron is therefore a respiratory food. Now, muscular strength and activity is in proportion to respiratory activity, and the extent of respiratory surface. Insects have more proportionate muscular strength than mammals, because they have a larger respiratory surface. And so it is throughout the animal kingdom. When the blood corpuscles, the oxygen carriers, are not sufficiently fed with iron, muscular weakness ensues. Thus, anæmia is a cause of muscular weakness; and the rationale of iron relieving the symptom is quite an evident one.

Our knowledge of the action of restoratives leads us to believe that they are the only drugs which can act as prophylactics. We cannot understand how a purely foreign body can enter the system and prevent disease. We know that we cannot prevent syphilis by giving mercury. We can see, however, that a substance which is a normal constituent of the economy may be given at a time when there is an especial drain on that principle, and thus prevent pathological changes which its diminution or absence might cause. The study of the use and action of cod-liver oil may lead us to conclude that this supplies a proximate principle to the economy, and may be used both to supply and prevent a diminished amount of that substance in the body.

History shows that cod-liver oil has been used from a very ancient date. Its extensive use, however, dates from 1849, when Bennett introduced it as a remedy for phthisis. Being a very complicated body, it was at first thought that its value was due to some of its peculiar chemical constituents. This is, however, hardly possible. Several of its organic constituents, such as the fatty acids, are the result of the chemist's manipulations. The inorganic constituents are so small in quantity that we should have to use homœopathic theories to suppose them to have any practical effect. Another theory is that the special action of the oil is due to its greater diffusibility, this being caused by the presence of biliary salts in it. This, however, is a false inference; for, in the first place, absorption is only one element, and we must explain the action afterward. Furthermore, it has been shown that emulsions of sweet-oil with ox-gall do not act as well as cod-liver oil, although very diffusible; and finally, it has been also shown that the lightest and purest oils, those freest from biliary constituents, are the best. The most satisfactory theory, therefore, is to suppose that the oil is allied in its composition to the highly complex fat of the blood, and that it supplies a natural constituent of that fluid. This theory is supported by the fact that cod-liver oil increases the number of the red blood corpuscles. Now, it has been shown that the corpuscles contain the greater part of the fat of the blood, the proportion as given by some chemists being three in the corpuscles to two in the plasma.

From analyses of the blood of the portal and hepatic vein it would appear that in the passage of the blood through the liver, some of the fat of the serum is incorporated into the corpuscles, and it may be one of the functions of the liver to do this. The relative importance of fat in the blood is shown by analyses. There is double the amount of it that there is of iron.

The next question is, what is the business of the fat in the corpuscles? And here physical laws come to our help. By these, fat is shown to contain a very great amount of stored-up energy. A pound of ordinary tallow, for instance, has more stored-up energy than a pound of coal, or a pound of gunpowder. It contains more energy than albumen also, in the proportion of 38 to 18. The great business of fat, therefore, is to supply force. In the embryo a great amount must be required, and the late Mr. George Lewis was even led to propound the preposterous theory, that the sole function of the spermatozoa was to furnish to the ovum a highly organized form of fat. He based this idea on the fact that spermatozoa are dissolved by ether. Fat bears much the same relation to the tissue-cells that steam does to the steam-engine.

With this view of the function and importance of fat, we turn to see what tissues contain the most of it in their composition. These we find to be the voluntary muscles and the brain. The brain, for example, contains 75 per cent. of water and 25 per cent. of solids, of which latter, 15 parts consist of fat. The nervous tissue uses more fat than all the other tissues put together. Of course, adipose tissue is not to be reckoned in this connection, for it is practically stored-up fat and not a user of it.

Now, in view of this demand for fat on the part of the nervous system, we may study with special interest that period of childhood when the nervous system is growing most rapidly and when the demand for fat is greatest. Between the end of lactation and the sixth year, the brain grows faster than at any other time. By the seventh year the head has often attained nearly its full size. Mothers are sometimes alarmed at the big heads of their children, and think that there must be something wrong about it. During these years the child acquires more than at any other period of his life. His perceptions are quickened, his memory taxed with the acquirement of language and all kinds of knowledge. The brain works better than it ever will again. All this puts a drain upon the system which renders the child peculiarly susceptible to certain diseases. After the ninth year, the muscular system takes a start and its development becomes very rapid.

Now the rapid growth and great functional activity of the nervous system makes a demand upon the food-supply, and especially the fat. These special demands may lead to the impoverishment of other tissues. And those tissues will suffer first which are the least highly organized, and receive the least vascular nourishment. Thus we have resulting the corneal ulcer; then the cartilages degenerate, the epithelium of the skin and mucous membranes develops a depraved or diminished vitality. Scrofulous sores appear. Once establish a sore and the lymphatic glands become enlarged. For it is probable that the scrofulous enlargements of glands are caused by some previous sore with which the lymphatics connect them.

If the above views are correct, then the utility of giving cod-liver oil at this period of life is shown to have a logical basis. And we ought not to wait until the symptoms of starvation appear before giving the oil. The speaker had been in the habit of giving cod-liver oil to healthy children between the ages of two and seven, and he believed with benefit.

The usefulness of cod-liver oil in nervous diseases is also very apparent.

The paper being open for discussion,

Dr. S. Caro said that he agreed with the reader of the paper in thinking that cod-liver oil is of value as a prophylactic, aad that it is to be regarded as a food rather than a medicine. He had known a poor family who were supplied with cod-liver oil through the kindness of a druggist, and who lived upon this to a large extent for a time. A girl in this family, which was a tuberculous one, had been suffering from chorea. While taking the oil she had recovered from it.

In the speaker's native country olive oil was much used as an article of food, and it was very nutritious. In the monasteries it was much used by the monks, especially in times of fasting, and the monks are, as a rule, quite fat.

Dr. Sell referred to the value of olive oil. He thought that this and butter ranked next to cod-liver oil in nutritive properties. He related the case of a female physician who had suffered for a long time from constipation and a whole train of attendant evils. She became too weak and emaciated to study or work. Finally, a diet, of which olive oil was a large part, cured her. Just before the siege of Paris one could see how much olive oil was taken to supplement the scarcity of other food. Dr. S. had found the external use of cod-liver oil with children of value. He also spoke highly of the emulsions of oil with maltine and pepsine or pancreatine.

Dr. Thomson said, in reply to a question by Dr. White, that the best time to take the oil was about half an hour or an hour after meals.

Dr. Richards spoke of the necessity sometimes of having a cheap substitute for cod-liver oil. He had known whale-oil to have been taken with good effects.

Dr. Farnham spoke of the value of cod-liver oil in lupoid affections, especially when it was taken in large quantities—as much, for instance, as two pints a day. He had known of cases which did not get any better under a pint a day, but showed marked improvement when the quantity was doubled. He had himself taken nine or ten ounces a day without any digestive disturbance. It increased his weight very much.

At the close of the discussion, it was announced that $500 had been turned over to the Academy from the estate of Dr. White.

It was voted that the next regular meeting be omitted, and that the Academy adjourn to the third Thursday in June.

* * *

The English Conjoint Examining Board Scheme.—For some years the medical press and a number of the medical colleges of Great Britain have been trying to secure a Conjoint Board of Examiners before which all medical graduates shall appear to obtain their licenses to practice. The delay and uncertainty regarding the establishment of this board has finally led the Royal College of Surgeons to pass a resolution withdrawing from the scheme. It now will endeavor to secure the voluntary organization of such a board among as many colleges as possible. This action of the college is regarded as a severe blow to the original project, and as being unwise and hardly warranted.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, March 23, 1880.

Dr. H. B. Sands, President, in the Chair.

THE TUBE IN TRACHEOTOMY.

Dr. Jas. L. Little reported a case, with remarks, of tracheotomy for croup, in which the tube could not be removed until four months after the operation.

Dr. G. A. Peters remarked that he had been unable to see any advantages arising from the use of the fenestrated tube; therefore, had not used it. He could understand its disadvantages.

The President remarked that the great advantage claimed for it was that it enabled the patient to speak.

Dr. Peters thought the disadvantages were so great that they could not be overcome by that single advantage.

Dr. Markoe remarked that that advantage was considerable when the patient was compelled to wear the tube permanently. That when the operation was done, for example, for ulcerative laryngitis, it filled so nearly all the trachea that the patient could not speak without closing the external orifice. That was the theory upon which it was used: but he could well see that it might be a source of irritation both by strangulating the granulations in the opening, and by the rubbing backward and forward of the tube. He thought Dr. Little's suggestion was desirable and practicable.

Dr. Peters asked Dr. Markoe if he desired to use a tube as large as the trachea.

Dr. Markoe replied that he had not paid special attention to that point, but had supposed the tubes nearly filled the calibre of the trachea. He did not wish to have the tube fill the trachea entirely.

Dr. Mason—If they do fill the calibre of the trachea entirely, are they not more likely to produce ulceration?

Dr. Markoe—Quite probably.

Dr. L. A. Stimson asked Dr. Little if he thought that the presence of a fenestrated outer tube was sufficient to excite the growth of granulations.

Dr. Little replied in the affirmative. He also referred to a case in which a fenestrated tube produced erosion sufficient to open a vein, and the patient died from hemorrhage.

Dr. F. H. Hamilton remarked that he remembered the report of the case referred to by Dr. Little, and his impression was that a careful autopsy was not made. His suspicion at the time was that it was uncertain whether hemorrhage came from tissues pressing into the fenestra, or from the extremity of the instrument producing some excoriation at a point lower down.

Dr. Keyes referred to two cases in which the patients wore the tubes permanently. Neither tube had a fenestra, and both patients could speak without closing the external opening. One patient was a child three years of age, who wore out three or four solid, heavy tubes. The other patient was an adult male.

Dr. Markoe remarked that he did not wish to favor the fenestrated tube especially, but simply mentioned the ability which it gave the patient to speak as the great reason assigned for its use in cases in which the tube was to be worn permanently. He then referred to a patient who was operated upon in the New York Hospital, wore the tube permanently, and who was made to speak so as to be understood, until he closed the opening with his finger.

Dr. Hamilton remarked that he had always supposed there was more than one purpose in the use of a fenestrated tube; that it was not entirely for the purpose of enabling the patient to speak, but that it offered an outlet, occasionally, for sputum, when it might have become lodged in the external opening. In other words, it was an additional means of escape, which the patient could avail himself of in an emergency. He also thought there was another possible advantage, and that was with reference to the preservation of the integrity of the vocal cords, so that future phonation would not be so much embarrassed by complete disuse of the cords, rendering the voice feeble and husky, as it might be by using other tubes. He supposed that the fenestrated tube had a somewhat double function, and he thought that its advantages were quite equal to its disadvantages, which were somewhat speculative. He agreed with Dr. Little, that, if we could use a small tube, a fenestrated one was entirely unnecessary, but he could not see the special disadvantages of the instrument.

Dr. Markoe raised the question: Is there not another use contemplated in the fenestra in this respect? In most cases the operation is performed for obstruction of the larynx which has come on suddenly and rapidly, and which we hope will disappear if the patient can be kept alive long enough for the removal of the morbid condition upon which the obstruction depends. The fenestra enables us to ascertain whether or not the opening of the glottis is clear, so that the patient can breathe through it, thus affording an indication as to when the tube can be removed. He then referred to a case now in the hospital, in which the patient had been wearing a tube for several months, and every time any attempt was made to remove it there was at once manifest danger of strangulation.

The President remarked that Dr. Little's case possessed special interest because of the existence of granulations which rendered the removal of the tube not only difficult, but dangerous. He had had a similar experience in one case, a case also of successful tracheotomy for diphtheritic croup, occurring in a child three years and eleven months old, the daughter of Dr. Westcott. True diphtheritic croup attacked the tonsil, extended into the larynx, and when he saw the child in consultation, he found the chances of recovery so slight that he did not recommend the operation, and declined to perform it. On the morning following the consultation, the father of the child came and asked him to go and open the child's trachea at once and at all hazards. Dr. Sands went immediately, found the child moribund apparently, but lost no time and opened the trachea below the isthmus of the thyroid gland, and inserted a tube which was not provided with a fenestra. The relief was, as usual, prompt and complete, but at that time he did not expect more than temporary benefit from the operation. The child was exceedingly ill, apart from the tracheal disease, and was not removed from the table for several days. There was no further tracheal obstruction, however, nor did the disease extend into the smaller tubes. There was scarcely any hope of recovery for ten days. The child took three ounces of brandy every twenty-four hours, for a number of days in succession. The operation was done on the 17th of May, and on the 1st of June the child seemed so well that Dr. Sands ventured to remove the tube, without suspecting the trouble which was to follow. Within a minute of the time when the tube was removed, symptoms of asphyxia showed themselves, each attempt at inspiration being accompanied with marked depression of the edges of the tracheal wound, and the situation was so threatening as to call for an immediate replacement of the canula. On the following day the tube was removed, with the same result. The obstruction was seen to be due to the presence of an abundant exuberant granulation which was closely attached to the upper semi-circumference of the wound in the trachea, and the mass was sufficiently large to act as a ball-valve when the tube was removed. The nature of the obstruction having been recognized, it was advised to treat the granulations by making a local application of nitrate of silver in solid stick. The granulations gradually melted away under the effect of the caustic, and finally, on the 20th of June, one day less than five weeks from the time when the operation was performed, the tube was permanently removed. Even then the child's breathing was embarrassed, and the face became a trifle blue; but presently respiration became more tranquil, and the tube was not reinserted. He had no doubt that in the case related the granulations were effectually disposed of by the solid stick of nitrate of silver; because, although some time elapsed between the first and the final removal of the tube, there was a manifest improvement every time it was removed after the use of the nitrate of silver was begun; it could be observed that the mass of granulations was smaller and smaller as examination was made.

The case showed that the granulations might prove to be a serious obstruction when a non-fenestrated tube was used.

As regards the size of the tube, he would say that a small tube was better than one that would fill the trachea. An English surgeon had taken pains to measure the sectional areas of the rima glottidis and the trachea, and had found that the former was always less than the latter; proving that, physiologically, it was unnecessary to have a tube of maximum size in order to allow sufficient air to enter the lungs, and the disadvantages of a large tube certainly were very great.

With regard to the proper time for removing the tube after the operation for croup, he thought attention should be paid to its removal at the earliest moment practicable, for granulations did not begin to grow immediately after the operation—possibly not until two or three weeks had elapsed. Recently he performed an operation upon a child, seven or eight years old, on account of membranous croup. At the time when the operation was performed suffocation seemed imminent, but afterward the child did so well that on the fourth day the tube was removed, its removal not being followed by dyspnœa. Dr. Sands thought that if the tube had been allowed to remain some days, perhaps a week longer, probably the same trouble on account of granulations would have been experienced as occurred in Dr. Little's case, and in the recorded cases of some other observers. Dr. Sands had no doubt regarding the efficacy of nitrate of silver in disposing of the granulations, and of the early removal of the tube in preventing their formation.

Dr. Keyes asked if any member had seen such granulations occurring in an adult.

Dr. Markoe referred to Dr. Buck's case in which the same trouble occurred in an adult, and the granulations were treated as Dr. Sands had mentioned, and successfully. In that case the mass could be seen distinctly as a large ball or flap as the tube was removed.

Dr. Stimson referred to a case of rupture of the aorta into the trachea, in which a bunch of granulations an inch long, and fully one-third of an inch high, was found at the edge of the ulcerated opening. The case illustrated how rapidly such masses might be formed.

The President remarked that it seemed probable the trachea was a place where exuberant granulations were very likely to form. He recalled a case occurring in Bellevue Hospital in which tracheotomy was performed above the isthmus. The patient was an adult woman. A tube was inserted, but no respiration occurred through it. The situation being very alarming, and the patient being likely to die at once, he took a probe-pointed bistoury, and, introducing it into the opening, cut directly downward through the thyroid isthmus and two or three tracheal rings, and then there was free respiration. The edges of the wound were held apart, and, inserting his little finger, he passed it upward into the larynx, which he found completely filled with granulations that had formed about a syphilitic ulcer below the level of the vocal cords and the level of the first opening.

Dr. J. C. Hutchison remarked that he uniformly used Durham's tube, and the great advantage it had was its shape. The end did not impinge against the trachea, and it could be made to change its position. Instead, however, of using the lobster-shaped inner tube, he used a modification, which was much less objectionable than that part of the original instrument. The modification consisted simply of a piece of silver wire so wound that it could be easily introduced.

The President remarked that the tube had a movable collar so that it could be moved, not only in an antero-posterior direction, but it could be rotated, and thus the position of the instrument could be changed, thereby preventing ulceration from pressure. The liability of the tube to escape in consequence of the short length of the vertical piece was perhaps one of its objectionable features.

Dr. Hutchison remarked that he had not experienced any inconvenience in that particular, for he had always watched it very carefully.

PUNCTURED WOUND OF THE SKULL.

Dr. G. A. Peters presented a button of bone removed by a trephine from the skull of a boy 17 years old, who gave the following history: While passing under the elevated railroad something dropped and struck him upon the top of the head. He thought it was a bolt. He was able to walk to the Chambers Street Hospital, a distance of about half a mile from the place where the injury was received, and from there he was sent to the New York Hospital where he came under Dr. Peters's observation. He presented no symptoms, and said that he felt as well as he ever did. On examination a small punctured wound of the scalp was found, so small that it would not admit the end of his finger. It was situated near the crown.

On introducing a probe and making careful manipulation, he felt certain that he recognized a depression in the bone. The patient was etherized and Dr. Peters made a cervical incision, exposed the skull, and found a spot where the bone had been driven bodily in front of the weapon by which he was struck. The external table was depressed over a space about one-third of an inch in diameter. The trephine was used, the skull was very thin, the dura mater was not injured, but in elevating the button a small portion was left behind. That was readily removed, and consisted of a portion of the internal table, about the size of a finger-nail, that had been scaled off and lay loose upon the dura mater. April 13th, Dr. Peters reported that the case had progressed favorably, that no accident had occurred, and that the patient was about ready to be discharged from the hospital as cured.

Dr. Markoe referred to a case, closely allied to that of Dr. Peters, which had the following history: About seven weeks ago he was summoned in great haste to see a young man who had shot himself. He was twenty-six years old, and told Dr. Markoe that, some hours before, he shot himself by holding a pistol near the side of his head and firing six times. After the shooting he called a waiter, told him that he had shot himself, and also told him to go for a doctor. On examination six openings in the integument were found, all above the zygoma, and within a space of the size of a silver half-dollar, except one which was a little below the zygoma. He explored them all, and found that only one of the shots had implicated the skull, and that was one nearly in the centre of the cluster. It had evidently perforated the skull about half an inch from the edge of the temporal muscle, and just below the temporal ridge. The opening was precisely like that seen in Dr. Peters's specimen, and was made by a pistol-ball, calibre 22. In exploring the wounds, he laid open all the space invaded by the different balls, traced them, and removed three.

Another he accounted for by the ecchymosis of the eyelid, and supposed it had lodged in the back part of the orbit. There were, however, no symptoms of injury of the eye. The fifth ball he found just within the muscular substance and just below the coronoid process of the lower jaw, but it was perfectly innocent and gave him no pain. The sixth was the one which he made out had perforated the skull.

The points of resemblance in the two cases were these: after exposing the skull and cleansing the wound, he could see at its bottom the edges of such a piece of bone as seen in the specimen presented Of course, it was impossible to remove that little piece through the hole already made; so, with the rongeur, he gnawed the bone away sufficiently to enable him to get beneath the edge of the depressed fragment and lift it out. It had sharp edges, but, happily, they had not been pressed against the dura mater so as to cut it. The patient had no symptoms at the time, no symptoms afterward, and made an apparently perfect recovery.

Dr. Peters recalled a case in which he trephined by gnawing the bone away, and removed several pieces of depressed bone, both the internal and external tables being involved. He then searched as far as he thought it safe about the edges of the opening with a probe, and could not find anything. Within a few days after the operation the man developed grave symptoms and died.

Autopsy revealed a portion of the internal table about as large as the thumb-nail, and nearly an inch from the apparent fracture. It had been knocked off, had turned up on end, and had sawed into the brain. He removed everything which was apparently fractured, and yet a piece of the internal table an inch away was depressed, and caused the man's death.

Dr. Hamilton remarked that it was a rule, with but few exceptions, that in gunshot fracture of the skull the inner table was more extensively broken than the outer. The law was so general, if not universal, that he deemed it unsafe to attempt to elevate the inner table without resorting to the trephine. He presented the rule as an argument against the use of a rongeur.

Dr. Markoe remarked that the incisions through the temporal muscle in his case were necessarily quite extensive, and must have been much more liberal had he wished to use the trephine.

Moreover, in reply to Dr. Hamilton's argument, he thought as large an opening could be made with a rongeur as with a trephine, and, as he thought, quite as safely. The suggestion with regard to the size of the opening he thought was a good one, but he did not think that Dr. Hamilton's criticism with regard to the instrument was quite sound.

Dr. Peters preferred a rongeur to a trephine when the edges of the opening in the bone could be elevated sufficiently to enable him to begin. He could make a cleaner opening with the rongeur than with the trephine.

Dr. Hamilton said that that answered his objection to the rongeur, if it could be done.

Dr. Markoe remarked that he was very careful to go beyond the piece depressed before attempting to elevate it.

The President asked: What became of the bullet?

Dr. Markoe replied that he supposed it entered the cranium and became encapsulated. He thought it went between the dura mater and the skull. With regard to that point, however, another case was suggested. He was called some years ago to see the son of a physician who had accidentally been shot with a pistol carrying a ball of 22 calibre, in almost exactly the same situation as in his case just related. The fracture was very nearly similar to the one exhibited in Dr. Peters's specimen. About one-third of the bullet could not be accounted for. He supposed that it had penetrated the bone. Moreover, the dura mater was penetrated and he could pass a probe into the brain-substance for a certain distance —say one-third of an inch. He felt perfectly sure that a certain number of grains of the *bullet* were imbedded in the brain; but the boy never had a single bad symptom.

Dr. Stimson referred to a case observed by Dr. Van Buren, in which a boy was struck upon the head with a piece of plank through which a nail had been driven. One end of the nail was buried in the boy's head, and when he presented himself it was sticking out and required considerable force to extract it. There was not the slightest symptom produced.

Dr. Peters referred to a case seen in the New York Hospital, where a fragment of wood had been driven into the brain about one inch through the bones of the skull and was firmly imbedded, but by gnawing away with a rongeur the bone surrounding it, he removed the splinter. The patient recovered.

Dr. Hutchison referred to a specimen which he presented to the N. Y. Pathological Society. It was the brain of a child who upon the fourth of July was shot with a toy cannon, the ball entering the head just behind the right ear. A probe passed in, without hinderance, two inches. The child had no bad symptoms at all. It subsequently died from scarlet fever, and at autopsy it was found that the ball had traversed the posterior lobes of the cerebrum, but he was not able to find the bullet.

Six months subsequently, the brain was examined more carefully, when the ball was found about two inches in front of the point at which it emerged from the brain upon the left side. It had struck the skull, glanced forward, and buried itself in the brain.

Dr. Hamilton referred to the following case: Some five or six years ago he was called to Hartford, Conn., to see a man who had shot himself, or had been shot with a Wesson pistol, and, after receiving the ball in his forehead, walked home, and subsequently began to suffer very moderately from cerebral symptoms. When sitting quietly the activity of the brain was undisturbed. He had slight vertigo, and was unable to walk. The opening in the bone was still free, and he was able to carry a probe, without resistance, into the cranial cavity fully three-fourths of an inch beyond the margin of the opening in the skull. The ball was not discovered. A year subsequently the man was well and attending to business.

COMPOUND FRACTURE OF THE ELBOW.

Dr. Lange presented the specimen, illustrating the separation of both epicondyles of the humerus, and referred to at the last stated meeting. He also presented the patient from whom the specimen was removed.

Dr. Hamilton remarked that the case should not go upon record as a simple fracture of the external epicondyle, but as a separation of the lower epiphysis accompanied by separation of the external epicondyle, and a compound fracture.

With reference to the question, Why a resection? he would say that success in resection depended somewhat upon the extent to which the bony surfaces were removed; for allowance must be made for contraction of the muscles. He thought the boy would not have had so good motion at the elbow if resection had not been practised.

Dr. Lange remarked that another fact which induced him to resect was the contused condition of the portion of bone removed.

The President remarked that, evidently, not too much bone had been removed, because there was no gap between the extremities of the bones.

The Society then proceeded to the transaction of miscellaneous business.

CONNECTICUT MEDICAL SOCIETY

Eighty-ninth Annual Convention, held at New Haven, May 26 *and* 27, 1880.

Wednesday, May 26—First Day.

The eighty-ninth annual convention of the Connecticut Medical Society was opened May 26th, at three o'clock, when the fellows' meeting was held. About sixty fellows were present. The attendance upon the convention is by delegates or fellows, who are appointed by the respective subordinate societies. The convention holds its sessions in the Common Council chamber, City Hall, New Haven. Dr. A. R. Goodrich, of Vernon, presided, his health being sufficiently restored to permit the discharge of the duties of the office. His presence and improved health was a source of great pleasure to the Society. The attendance, though not large, was a fairly representative one, all sections of the State being represented.

The President in his address expressed his gratification at being able to officiate, and invited attention to the past, present, and future relations of the Society. He referred to the important sanitary relations the Society bore the State, and pointed to highly valuable work the Society had done for the State in the past; a part of this work being the shaping of sanitary legislation for the protection of the powerless and the development of the weak-minded; and another part being the origin and promotion of legislation regarding the collection of vital statistics. The address proceeded: "In determining the degree and extent of fostering care and kindly criticisms which may properly be exerted in these directions, we need no volunteer aid and cannot tolerate any foreign influence with our domestic affairs until our own incompetency is clearly demonstrated." Aid or countenance, it was advised, should be withheld from all schemes of doubtful expediency or questionable philanthropy. "The State Board of Health, still in its infancy, deserves to receive the active sympathy and support of every intelligent citizen. It has hopes of a brilliant future in the possibility of conferring upon the commonwealth benefits of inestimable value, and it should at all times receive the hearty co-operation of the Society in its wise efforts to promote, by all lawful means, the public health, and thus increasing, as no other agency can, the value of life and with it the great working capital of the State.

"The progress already made in this country in sanitary science is very pleasing; twenty-three States have already established State boards of health. Iowa, New York, and North Carolina have since our last meeting fallen into line.

"In view of the facts which have transpired in the State the past year, I would call your attention to the free and unlimited sale of poisons, especially those most commonly used for suicide and criminal purposes. This indiscriminate sale should not be allowed in the State. Every safeguard that the law can provide for the protection of life and the prevention of crime should be furnished.

"Preventive medicine, like conservative surgery, will be considered in the near future as affording the highest possible illustration of professional skill.

He commended the action of the legislature in placing the department of vital statistics under the care of the State Board of Health, but mentioned the carelessness in keeping the registers, which are under the charge of town officials, and condemned the manner in which they were sometimes used to give publicity to facts in the history of individuals or families that were recorded strictly for statistical or genealogical purposes, or for the maintenance of inherited rights.

"It should be remembered that these records contain the private histories of all persons who are, or may be, born, married, or dead, in the State, information which the public has no right to possess, and which the State even has no right to publish.

"The present status of medical expert testimony is a reproach to the profession, and it is high time some steps were taken to remedy the most glaring evils connected with this subject. Either consciously or unconsciously the expert becomes the medical advocate of the person by whom he is called, instead of an impartial witness of the facts as best known to medical jurisprudence; and it is to be feared that too often the fee is made contingent upon the amount of damages secured through the testimony of the expert. It too often happens that men are summoned as experts who have no special fitness, either by position or acquirements, upon subjects that require the devotion of a lifework to comprehend and elucidate, much more to decide *ex cathedrá*."

The address, in its concluding pages, asked attention to the "indiscriminate practice of medicine by the ignorant and unqualified, terms applied to impostors and uneducated persons," in regard to which a bill was before a recent legislative body, and which it was thought would have passed had it been suitably amended.

He paid a fitting tribute to Dr. H. M. Knight, late superintendent of the School for Imbecile Children at Lakeville. This institution was originated and established by Dr. Knight, who devoted his life to the cause of these unfortunates. He lived to demonstrate the truth of his ideas and the value of his methods, and had become a recognized authority in that department. His last public work was in superintending the establishment of a similar institution in one of the Western States. He died suddenly, away from home, at a health resort, from a spinal affection. His death was a loss not only to the State, but to the country as well.

Allusion was also made to the death of Dr. B. H. Catlin, of Meriden, a prominent member of this Society, formerly its president. He had also been a vice-president of the American Medical Association. Also to the death of Dr. A. B. Haile, of Norwich, an influential and prominent member of the Society, always zealous for its welfare.

The several points included in the President's address were briefly discussed, and committees were appointed to report at the next convention, as follows:

On Expert Testimony, its Uses and Abuses, the Remedy, etc.—G. W. Russell, of Hartford; S. G. Hubbard, of New Haven; William Deming, of Litchfield.

On Vital Statistics.—M. C. White, of New Haven; W. A. M. Wainwright, of Hartford; A. M. Shew, of Middletown.

On Sale of Poisons.—Rufus Baker, of Middletown; William Deming, of Litchfield; S. H. Bronson, of New Haven.

The committee appointed last year to report upon a set of resolutions which recommended the appointment of commissioners for the insane in this State, defining their duties and powers, and also a change in the law of the State which requires a sworn statement of insanity from one reputable physician only, as requisite for the commitment to an insane asylum, reported as follows:

Whereas, We consider that our information upon the questions involved in the resolutions referred to is not sufficiently extensive to enable us to recommend any decided action at present; we submit the following resolution:

Resolved, That a committee of three, conversant with the history of insanity, should be appointed by the State Convention to investigate the subject of lunacy commissions in other States as well as in foreign countries, their history, aims, and results for the information of the next annual convention.

Moses C. White, New Haven,
N. Nickerson, Meriden,
Gurdon W. Russell, Hartford,
C. A. Lindsly, New Haven,
C. W. Chamberlain, Hartford.

The report was accepted without debate. The expediency of a change in the law regarding commitments for insanity was unanimously conceded. The following were appointed by the President as members of the committee recommended in the preceding resolution: A. M. Shew, Middletown; H. P. Stearns, Hartford; D. A. Cleaveland, Middletown.

Drs. A. N. Bell, of Garden City, and E. C. Seguin, of New York, were elected honorary members.

The committee appointed last year on the recommendation of President Carleton, on the metric system, reported the following resolutions, after a brief but favorable review of the subject:

1st. That the Connecticut Medical Society adopt the international metric system, and will use it in its transactions.

2d. Requests that those who present papers at its future meetings will employ this system in their communications and reprints thereof.

3d. Requests the medical boards of State hospitals and asylums to adopt the metric system in prescribing and reporting cases, and that the faculty of Yale Medical College adopt it in their didactic, clinical, and dispensing departments.

4th. Requests the physicians to familiarize themselves with the system, and help the druggists in its application.

E. B. Lyon, New Britain,
C. J. Fox, Willimantic,
E. C. Kinney, Norwich.

The resolutions were taken up separately, and the first, second, and third rejected after considerable discussion. The fourth was passed.

Report was made by the committee on the medical examiner system, in place of the coroner, the committee being Dr. Wainwright, of Hartford, Dr. Worden, of Bridgeport, and Dr. Chamberlain, of Hartford. The report stated that the committee visited Boston, being present at the annual meeting of the State society. Massachusetts has the medical examiner system, having substituted it for the coroner system. Its working was pronounced eminently satisfactory, and a great improvement over the old; but as the result of consultation made with eminent lawyers of this State, etc., it was deemed advisable not to recommend the substitution in this State at present.

The report of the Treasurer showed a better condition with reference to the tax laid in 1879 than in any year since he had been in office, and it is doubtful if any year previous can present an equally good showing; with money in hands of clerks ready for transmission; but little over thirty dollars remain uncollected. This is due to the zeal and activity of the county clerks. The Treasurer commended especially Drs. C. W. Gaylord, of New Haven County, and F. M. Wilson, of Fairfield, for their efficiency in a hitherto difficult field. This leaves a balance of about three hundred dollars in the treasury.

The following officers were chosen for the ensuing year: *President,* G. L. Platt, Waterbury; *Vice-President,* Wm. Deming, Litchfield; *Treasurer,* F. D. Edgerton, Middletown; *Secretary,* C. W. Chamberlain, Hartford.

Committee on Matters of Professional Interest: W. A. M. Wainwright, M.D., L. S. Wilcox, M.D., W. L. Bradley, M.D.

There were four members to be chosen on the Committee of Examination, as there had been three new professors appointed at Yale, and there was one vacancy caused by the death of Dr. J. E. Barbour, of Norwalk. The Society has a member on this committee for each professor in the Medical School, and this committee grant diplomas. The President of the Society is ex-officio President of this committee. The following were elected: G. H. Preston, Tolland; J. A. Cleaveland, Middletown; H. S. Fuller, Hartford;

C. E. Hammond, Portland; E. Baldwin, South Canterbury.

Committee to Nominate Professors at Yale Medical Department: G. W. Russell, Hartford; C. H. Pinny, Derby; R. S. Goodwin, Thomaston.

Committee on Publication: C. W. Chamberlain, Chairman ex-officio; F. D. Edgerton; G. W. Russell.

Dissertator: J. W. Lyon, Hartford. Alternate, N. Nickerson, Meriden.

THURSDAY, MAY 27—SECOND DAY.

The Convention assembled at 9.30 A.M. A. R. **GOODRICH** in the president's chair, C. W. **CHAMBERLAIN** at the secretary's desk. First in order, the Secretary, Dr. Chamberlain, presented his report, showing the membership to be 440, a net gain of twenty. The zeal and activity of the county clerks have been marked, especially those in New Haven and Fairfield counties. During the last four years there were forty-nine deaths, one loss by expulsion, and twelve by removal and dismissal. This year the new members are thirty-five, nine in Hartford County; twelve in New Haven County; eight in Fairfield County; one in Windham County; one in Litchfield County; two in Middlesex County; and two in Tolland County. The deaths were: Hartford County, one; New Haven, two; New London, two; Fairfield, three; Windham, one; Litchfield, one.

There has been a steady gain in membership during the last five years, notwithstanding an unusually high death-rate. The Society has lost fifty-two by death during the last five years, most of them old men, average age sixty-one, three years above the general average as given in the Massachusetts tables. The oldest ninety, the youngest twenty-nine; eight were eighty and over; thirteen, seventy and over. The accessions of new members have made good the loss and given a steady gain; the total gain in the five years, sixty-five.

Owing to the illness of the President, the usual annual address was omitted.

DR. A. M. WAINWRIGHT, of Hartford, Chairman of the Committee on Matters of Professional Interest, next reported that the health of the people of the State had on the whole been very good the past year, and there were no epidemics to report. At his request, the reading of his reports from the several counties was delayed until a more favorable occasion.

PROF. W. H. CARMALT presented a very interesting dissertation on "Some Limits in the Use of the Ophthalmoscope," in which he endeavored to save the instrument from its injudicious friends, who, by making such extravagant claims for its powers as an aid to diagnoses of cerebral, and, indeed, of almost every disease, by showing its true field, and the limits within which it was useful. Undeserved discredit had already been thrown upon a very valuable and indispensable instrument by these extravagant claims. While it has almost unbounded limits in determining ocular disease, it has no power to demonstrate the condition of the circulation in the brain, whether congested or anæmic, nor in the diagnosis of cerebral disease, as these abnormal conditions do not affect the intraocular circulation, in which there is no arterial pulsation. Considerable discussion followed.

Introduction of business, cases of interest and discussion, was next in order. **DR. F. WAYLAND BROWN**, of Woodbury, introduced the case of a boy, who, while playing about a bonfire, fell into it, receiving serious burns about the lumbar, gluteal, and post-femoral regions. When the accident happened, the child was but three and a half years of age. In treating him, Dr. Brown stated that 2,000 grafts of skin from other persons were made. The lad was closely examined by the physicians present, who seemed to be greatly interested in the case.

PROF. CARMALT exhibited a perimeter of his invention, to take the place of the more expensive instrument of Foerster, to show the actual limit of the visual field. The instrument was very warmly received when exhibited at the meeting of the Ophthalmological Society at Newport, and attracted considerable attention from all the oculists present, and all interested in ophthalmic work.

DR. H. P. STEARNS presented a very valuable essay on the Insane Diathesis, in which the border-lands of insanity were treated and discussed in a masterly manner, and the causes that are at work in producing the great increase in nervous diseases and insanity were, to a great extent, presented and discussed; prominent among these he placed the faulty educational system now in vogue, the high-pressure system demanding attention to so many diverse and intricate subjects, overtasking the brain—often under the most unsanitary surroundings that could be devised. Not only was the brain overtasked, but the eyesight strained by imperfect or ill-adjusted supply of light, until nervous irritability, as well as impaired vision, were the resultants. The effects of too many hours of study, a rigid mechanical discipline, treating flesh and blood as if it were wood and steel, and the unsanitary surroundings and unhygienic regulations associated with school-life, were well presented. The resultant of insanity from ill-managed peculiarities and freaks, and other idiosyncrasies that are associated with the border-land of insanity, were well presented.

A very interesting essay on "Functional Diseases of the Nervous System" was then read by **DR. J. B. KENT**, of Putnam, in which he discussed the effect of overwork and mental strain, more especially as occurring in brain-workers, literary men, newspaper writers, business men with the responsibilities of a large and complicated concern resting upon them. The resulting insomnia, the resorts to stimulants and hypnotic drugs, and the resulting nervous irritability, brain-exhaustion, insanity and other nervous diseases, and brain-softening, were presented and discussed.

DR FRANK HAMILTON, an honorary member of the Society, who was present by invitation, discussed the treatment of Colles's fracture in his inimitable manner. He recommended light dressings, but one splint underneath the arm, padded so that there should be nothing immediately underneath the ends of the fractured bones, and then loosely bandaged. The hand should be left free and early motions encouraged. Where the patient could be trusted, the dressings should be removed at the end of the third week. The description of the fracture and its treatment were illustrated with specimens of fractured radii finely mounted.

DR. J. P. C. FOSTER then read a carefully prepared paper on the "Hereditary Transmission of Syphilis," in which he presented a thorough résumé of all that is now known upon the subject, also illustrations from his own practice and observation. Among the views advocated was that the child may be infected from the father without any infection of the mother, either prior to or during gestation. The paper was very well received.

DR. D. A. CLEAVELAND then read an essay, in which the ignorance of the profession generally concerning nervous and especially mental diseases and insanity were strongly condemned. As it is generally admitted that insanity is most amenable to treatment in the acute stages, and as it falls to the lot of the general practitioner to treat it in its incipiency, and too often through the overcrowded condition of our lunatic asylums, especially those for pauper patients, to whom health is the indispensable requisite for obtaining a livelihood, the importance of a better knowledge of the subject becomes evident; moreover, many of these cases have to be treated in almshouses, where they remain until all hope of cure is lost, even if there were any at the outset, through the lack of skill of the attendant as well as the lack of appliances. The power lodged in the hands of one physician in this State, of depriving a fellow-being of his liberty and of all civil and testamentary power, by declaring him insane, also demands a more thorough knowledge on the part of the profession, lest abuses should occur.

The paper was followed by considerable discussion, and, as before stated, a concurrence in the desirability of a change in the law concerning commitments to insane asylums, although no cases of abuse of this power have ever been brought forward in this State.

Several other essays were read by title only, as the hour for dinner had arrived: "Anomalies of the Eye as Aiding Diagnosis of Extra-ocular Disease," N. E. Worden, Bridgeport: "Chrysophanic Acid," C. J. Fox, Willimantic. Six or eight voluntary papers were read by title only, and referred to the Committee of Publication. The convention then adjourned to an excellent dinner given at Redcliffe's, and keenly enjoyed that and the social hours with invited guests that followed.

The next convention meets at Hartford, fourth Wednesday in June, 1881.

New Instruments.

A NEW FORM OF ASPIRATOR AND NEEDLE.

By A. M. PHELPS, M.D.,

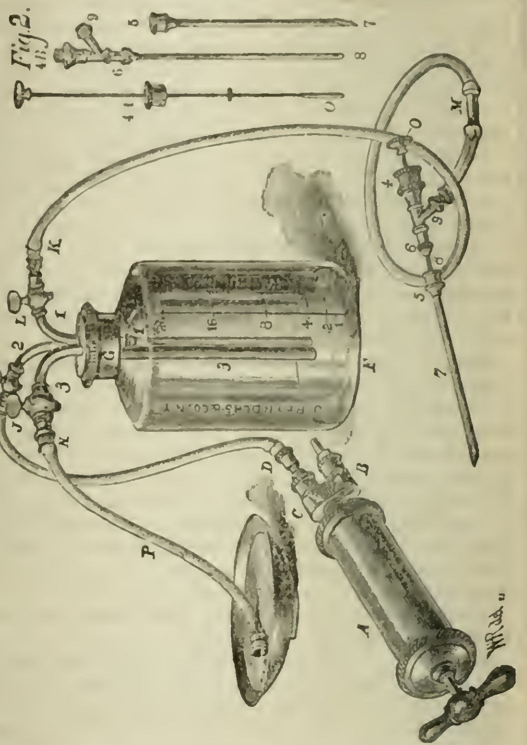
CHATEAUGAY, N. Y.

This instrument, which is a modification of Potain's, has been devised with a view to facilitate, as much as possible, the operation of aspiration. It is provided with a pump with two ends—one for aspiration, the other for injection—so constructed that either can be done without any preliminary preparation other than attaching it at the proper end, to accomplish what is desired of the two.

As the figure shows, three tubes emanate from the top of the bottle, one of which passes only through the cover of the bottle, and the other two to its bottom. The former is to be connected with the pump, and serves as a channel for air to be forced in or out of the bottle. Of the two tubes reaching to the bottom of the bottle, one is for conducting liquids into, the other for conducting them from, the bottle. Each tube is provided with a stopcock.

This arrangement forms an instrument which answers its purpose more readily than any other.

Supposing that an aspiration is to be made: the stopcocks L and J should be closed, the pump attached to the tubing D, at the end, designated by the backward-pointed arrow, showing that through it the air passes into the pump. The pump, upon being then worked, will produce a vacuum in the receiver F. When this is achieved, the stopcock H should be closed and L opened, after the needle has been introduced. As soon as the bottle is filled, it can be emptied by attaching the pump at its end B, closing the stopcock L and opening N. Upon working the pump, the contents of the bottle will pass out through P. By reversing this proceeding, an injection can be made without disturbing the screw cap G of the receiver—the receiver filled through P and emptied through K into the abscess.



It consists of three parts, as seen in Fig 2. The part 7 is slid over and O slid into the canula 8, the aspirator being attached to the lateral tube 9—7 is the cutting needle furnished with a rubber packing at 5, being shorter than 8; after its introduction 8 is pushed forward through it and the point is protected. The obturator is to dislodge obstruction in the needle during aspiration, and passes through a tight rubber packing at 4A. During aspiration it is drawn out beyond the lateral tube 9. The needle attached to the tube K shows it ready for the operation. In aspirating pus and effusion loaded with flakes of fibrin, I have not been disappointed in its use.

Exhibiting Pathological Specimens by Card.—A year ago the Pathological Society of London undertook a new feature in the conduct of their meetings. It consisted in allowing some specimens to be exhibited "by cards" on which short descriptions of the cases were written. Much valuable time was in this way saved. The society now reports that the plan, which was a tentative one, has been very successful. The hint might well be taken by other societies.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 4 to July 10, 1880.

Byrne, C. C., Major and Surgeon. Assigned to duty as Post Surgeon at Angel Island, Cal., relieving Asst. Surgeon Hubbard. S. O. 93, Div. of the Pacific and Dept. California, July 1, 1880.

Hubbard, Van B., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon at Alcatras Island, Cal. S. O. 93, C. S., Div. Pacific and Dept. California.

Kimball, J. P., Capt. and Asst. Surgeon. Granted leave of absence for twenty-one days. S. O. 63, Dept. of the Platte, July 7, 1880.

Winne, C. K., Capt. and Asst. Surgeon. To report in person to Commanding General, Dept. of the East for assignment to duty. S. O. 148, A. G. O., July 6, 1880.

DeLoffre, A. A., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon, Camp on White River, Colo. S. O. 144, Dept. of the Missouri, July 5, 1880.

Comegys, E. T., Capt. and Asst. Surgeon. Relieved from duty in Dept. of Texas, to proceed to Cincinnati, Ohio, and report arrival there by letter to the Surgeon-General. S. O. 148, C. S., A. G. O.

Reed, W., Capt. and Asst. Surgeon. His leave of absence extended one month. S. O. 146, A. G. O., July 6, 1880.

The following named Assistant Surgeons, recently appointed, will report in person to the Commanding Generals of the Departments set opposite their respective names :

R. G. Ebert, Department of the Columbia.
R. J. Gibson, Department of the Missouri.
R. B. Benham, Department of Dakota.
W. C. Gorgas, Department of Texas.
Norton Strong, Department of the Platte.
A. W. Taylor, Department of the Missouri.
S. O. 149, A. G. O., July 7, 1880.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending July 10, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

July 10, 1880.	0	6	28	4	21	36	0	0

The Medical School at Cambridge University, England, has been enlarged by the addition of some buildings. This school has never amounted to very much until lately. Now, however, considerable study in the elementary medical branches is done, and there were seventy students attending the course on practical anatomy and physiology last fall.

The Cause of Wool-Sorter's Disease, which causes deaths in England every month, is being investigated by the Local Government Board.

The Faculty of Rush Medical College, Chicago, at their last meeting, voted that after March 1st, 1883, all applicants for matriculation in the college shall be required to submit at least a certificate of an entrance examination to a literary school or college, or pass a written examination in natural sciences, arithmetic, and English, as a condition of admission to the college.

This move marks a substantial step of progress for the school.

Prof. R. C. Kedzie, M D., has been elected President of the Sanitary Council of the Mississippi Valley.

The Starling Medical College has increased its fees to $75.

Over Ninety-eight tons of Quinine are annually consumed. The cost is about twelve millions of dollars.

Cruelty to Women.—For some time *The Lancet* and other English medical journals have been showing up the cruelty of compelling shop-girls to stand on their feet all day. Public sentiment has at last been somewhat aroused in the matter, and a little improvement has begun. In some shops the girls are now allowed to sit down when not busy. In many of the large establishments, however, any rest is still denied them. There is such a demand for positions by women that the shop-keepers have it all their own way. A short time ago a place in the post-office, paying $3 a week, was vacant. Within twelve hours, 1100 applications were made. With such an excess of supply over demand, it is found difficult to do very much in behalf of the shop-girl.

A Medical Postal Microscopical Society.—It is proposed by the editor of the *American Journal of Microscopy* to establish a Medical Postal Microscopical Society for the purpose of interchanging prepared slides. Such a society has been in successful operation in England, among medical men, and there is a Naturalist's Club in this country which is organized for the same purpose. The plan is to place in circulation a number of boxes, so constructed that slides can be placed in them and be circulated by mail among the members of the society. These boxes are made so that it is almost impossible for the slides to be broken. The English society, though yet in its infancy, has succeeded very well. One of its members writes that most of the slides have been of a very high order; some sent by professional mounters and others the work of amateurs (medical men) are triumphs of section-cutting, staining, injection, etc. The writer further states that it is a great pity that slides illustrating rare forms of disease or original investigations into the causes of morbid action, should be seen by the comparatively small number of medical men who can attend the meetings of societies. The subscription to the English society is only $1.25; and for that sum each member has an opportunity to see a large number of rare and interesting specimens.

The plan of the society is a good one, and there is no reason why we should not introduce it here. There would be, to be sure, longer transportation necessary, and consequently more risk than in England. Doubtless few would be willing to circulate rare specimens unless there was a duplicate ; but even with this restriction, a Postal Microscopical Club could do much good.

The editor of the *American Journal of Microscopy* has undertaken to initiate the movement for organization, and any who wish to assist it, or know more about it, should write to John Phin, 14 Dey street, New York City.

The Library of the N. Y. Academy of Medicine will be closed during the evening in July and August of the present summer.

American Ophthalmological Society.—The sixteenth Annual Meeting of the American Ophthalmological Society will be held on Thursday, July 22d, at the Masonic Building, corner Church and School Streets, Newport. The morning session begins at 10 o'clock.

Richard H. Derby, *Secretary.*

Chian Turpentine in Cancer.—Mr. Alex. Marsden, Senior Surgeon to the Cancer Hospital, London, states that Chian turpentine has been extensively used in his hospital, in cancer of the uterus, breast, tongue, etc., but without benefit in any instance. Of the samples used only two proved to be pure, but the patients who took this kind did no better than the others.—*Brit. Med. Journ.*

The New York State Board of Health at a recent meeting passed the following resolution :—

Resolved: That in the best interests of the people at large, the State has made it the duty of the State Board of Health, now for the first time authorized by law, to call attention to whatever may secure sanitary improvement by better systems and methods of drainage, sewerage, and ventilation, vaccination, the supply of pure water, the prevention of the adulteration of food and of the pollution of wells, and the prevention of filth diseases and other destroyers of health and life, to the end that discussions, information, and the best sanitary measures may be had to avert danger. When it is understood that scarlet fever may be communicated by the breath in a second of time and from infected clothing not worn for a year, and that diphtheria often results from contact with impurities in earth, air, and water, parents and school-teachers will see the necessity of excluding children afflicted with or exposed to either disease from entering schoolrooms and all places where others would be endangered. All good citizens will also realize the danger from exposure to decayed vegetables, fruits, and other sources of sickness, especially when surface or subsoil wells communicate with water polluted by proximity to drains, cess-pools, and other filth. The State Board looks first of all to an enlightened and healthful public opinion to aid it in the important and responsible duties imposed upon it by the State."

The above resolution is excellent in spirit and correct in the facts. As a specimen of English composition, however, it is an agonizing piece of work.

Another resolution was passed requesting the various county officers in the State to call general attention to the provisions of the law creating the Board of Health.

Impure Bromide of Ethyl.—Dr. Carl Jungk, in the *Therapeutic Gazette*, has given the results of analyzing a large number of samples of hydrobromic ether. Among the samples examined were specimens of the ether used by Dr. J. Marion Sims and of that used by Dr. Levis in their fatal cases. The reactions of these demonstrated conclusively their entire unfitness for purposes of inhalation.

Prof. Lister is to receive the honorary degree of LL.D. from the University of Oxford.

The Hospital Sunday Collections in London this year amounted to nearly $100,000.

Dr. Charles T. Van Winkle, one of the oldest practitioners of New Jersey, recently died at his residence, Little Falls, N. J.

The Health of the City.—The city is reported by the health authorities to be in better sanitary condition than in any previous summer. The excessive heat, however, has produced an extraordinarily large mortality, especially among children. The number of deaths among those under five years of age had been nearly sixty a day up to July 12th. The following table will show the mortality and its relation to the temperature:

Week Ending.	Total Deaths.	Under 1 Year.	Under 2 Years.	Under 5 Years.	Mean Temperature.
June 5...	501	112	157	193	66.1
June 12 ..	479	144	189	211	70.7
June 19...	707	278	338	386	71.1
June 26...	1,038	529	664	713	78.6
July 3...	1,297	635	804	863	72.2

For the week ending July 12th, the temperature and mortality were as follows:

	Deaths.	Infants.	Max. Temp.
July 6....	135	..	79°
July 7....	144	..	80°
July 8....	127	..	84°
July 9....	135	..	85°
July 10....	134	..	84°
July 11....	106	..	86°
July 12....	134	72	85°

The number of deaths among children under five years of age has been from 49 to 67 per day. The average being about 60.

Of the mortality in the week ending July 3d, 59.83 per cent. was in tenement houses. Of the mortality among children under five years of age, 66.85 per cent. has occurred in the tenement houses.

This is at about the usual ratio throughout the year and it cannot be claimed that the tenement houses are made very disproportionately fatal by the high temperature.

In the week ending July 12th, the proportion of mortality in tenement houses was slightly increased.

The number of sunstrokes has not been very large. On July 9th, 19 cases of prostration from heat were reported. The average number has been about half a dozen.

Dr. Tanner's Fast.—On July 14th Dr. Tanner was reported to have gone for sixteen days without food. The amount of water taken is said to have averaged from half an ounce to an ounce a day. Four ounces were taken in the first nine days. Water is frequently used to rinse the mouth and wet the head and feet, but none is, apparently, swallowed. The amount of flesh lost has been a little less than a pound and a half per day. The temperature and respiration have been normal; the pulse has occasionally run up to 100, but not much beyond that point. The general condition has been very good. The faster walks about and converses freely. His mind has continued clear, but has become somewhat irritable. He complains of no pain or great suffering; but he is restless and his countenance bears a pinched look. There is a gradually increasing physical weakness and tendency to doze or lie quietly on the bed.

There has now been established a watch of eight regular physicians, in conjunction with the eclectics. All the watchers seem to feel great confidence that the fasting man is in earnest and has taken no food.

Original Communications.

TRACHEOTOMY IN CROUP:

WITH REMARKS ON

THE PATHOLOGY, DIAGNOSIS, PROGNOSIS AND TREATMENT OF THE DISEASE, AND THE CAUSES OF DEATH IN FATAL CASES; WITH A REPORT OF THIRTY-FIVE OPERATIONS.

By JOHN H. RIPLEY, M.D.,

SURGEON TO CHARITY HOSPITAL: PHYSICIAN TO ST. FRANCIS'S HOSPITAL, NEW YORK CITY.

PART IV.

DURING the past few years I have met several prominent physicians who, after having performed tracheotomy for croup a number of times without success, were inclined to look upon it as an operation of doubtful efficacy. I had myself nearly reached that conclusion, when I was unexpectedly cheered by a recovery. Since that time I have never lost faith in its power to save life, although I have sometimes thought that the instances in which it would do this were rare. Now, however, after a more extended experience and observation, I am satisfied that it is not only often successful, but that, as a general rule, it is the only resource which does offer any hope in cases of grave exudative croup.

Diagnosis.—Some time ago I was present at the examination of a candidate for one of our city hospitals, when this question was propounded: "What is the pathognomonic symptom of membranous croup?" The trembling young doctor gave it up. "Seeing the membrane," instructively remarked the professor. Well, if by that assertion be meant "seeing the membrane in the larynx," then I fully agree with it; but if it be meant that when you have a patient with a croupy cough and membrane in the fauces, you necessarily have exudative croup, then I know that you will sometimes be mistaken. I have already seen two such cases, in which the laryngoscope showed entire absence of membrane in the larynx. And, if we may judge from the subsequent progress of cases, there must be quite a large number exhibiting these conditions, that either have no membrane in the larynx, or, if they have, it is of a thin, non-developmental character, so that it keeps up a slight laryngeal stenosis for one or more days, and then disappears without causing grave symptoms or demanding special treatment. Every physician who has had much experience has seen such cases. Some, that linger in this way for several days, ultimately develop into the gravest form of croup. The laryngoscope only can decide which are pseudomembranous and which simply inflammatory. During the last few years I have devoted considerable time to the study of the earlier manifestations of this disease, in a comparative way, in order, if possible, to find some one symptom, or set of symptoms, by which it could be differentiated from that affection which so closely simulates it at times, *catarrhal laryngitis.* But I do not believe it is always possible to tell which you have to deal with, even after two or three days' watching. In fact, I am forced to the conclusion that, occasionally, the inflammatory œdema of a laryngeal catarrh may go on to fatal obstruction. We know that it occurs in the adult, and I, myself, have seen two cases which would, undoubtedly, have terminated fatally, had they not been saved by tracheotomy. They are referred to elsewhere in this paper. I have also seen a child with this form of laryngeal obstruction in consultation with Dr. Geo. M. Edebohls. The symptoms persisted after a fair trial of both local and constitutional treatment, got worse, and tracheotomy was performed. The following morning respiration could be carried on freely through the larynx. This condition, however, I believe to be of exceedingly rare occurrence in children, and that those reported cases in which the autopsy did not discover membrane, were mostly undeveloped pseudo-membranous croup. The pitch and character of the cough, the quality of the pulse, the temperature, the presence or absence of catarrh of other organs, are the main points to be considered in making an early diagnosis, if no membrane be visible.

In *catarrh of the larynx* the cough is usually more or less moist, lower in pitch, and often changes its tone, owing to the expulsion of sticky mucus, etc. The pulse is frequent, but soft and compressible. The temperature is usually low, elevated only from one to three degrees F. It is more frequently associated with coryza and catarrhal conjunctivitis, and sometimes also with diarrhœa, bronchitis, or cystitis. The fauces may, or may not be congested. A history of similar attacks, if obtained, is also to be taken into consideration. Especially something like this: "Doctor, he always coughs croupy when he gets a cold."

In *primary croup* the cough is dry, high-pitched, ringing, and unchangeable as a rule. The voice, too, is generally hoarse from the first, whereas in the milder complaint it is often unchanged. The temperature is of a higher grade, 102°–103°. It is not often associated with catarrhal symptoms of other organs. The condition of the fauces is no guide. Time is often of great importance in arriving at a diagnosis. For example, if the history obtained is that the child has been sick three or four days with croupy cough and coryza, and is no worse at the time of your visit, the probabilities are that it is simple catarrh; and every day added without supervention of graver symptoms strengthens your opinion.

There is a class of inflammatory cases in which, after a few days of catarrhal symptoms, there is early and persistent dyspnœa, lasting sometimes for a week or even longer. Slight amelioration takes place during the day, but, as evening advances, the dyspnœa becomes again more marked. One who had not seen such cases would be almost certain to make a diagnosis of membranous croup. To avoid error in diagnosis it is only necessary to watch and to wait. It will soon be seen that, although the symptoms are severe, they do not progress; here again, too, the temperature is low.

My observation would lead me to believe that *retropharyngeal abscess* is also sometimes mistaken for true croup. The absence of fever and the characteristic craning of the neck should lead one to suspect, and a digital examination of the pharynx demonstrate, the true nature of the disease. Yet, I have known an instance in which a child was allowed to die of a supposed croup, when a simple puncture with a scalpel would have saved its life.

Spasmodic laryngitis, or *false croup*, as it is generally called, with its sudden, nocturnal, and severe onset, and its short duration, does not much resemble the more dangerous disease. But, after all, I have been able to find but a single pathognomonic symptom of true croup: *continuous and progressive laryngeal stenosis.* When once it has set in, like the temperature of the first days of typhoid fever, each succeeding evening finds it more advanced than before, although it may lull the fears of the parents by day.

The question whether there be a primary non-contagious, non-infectious disease, characterized by a fibrinous exudation upon the mucous membrane of the larynx and contiguous parts, and which kills only by mechanical obstruction, is still being discussed. Before my experience with these cases I was strongly with the affirmative. Now, I am consciously and conscientiously undecided. It has always seemed to me to be a strong argument in favor of the existence of a non-contagious croup that physicians in this country generally, until recently, since the prevalence of diphtheria, have recognized such a disease. One would expect that, from time to time, cases of contagion would have occurred sufficient to excite suspicion at least. Now, since diphtheria has been epidemic, inflammatory diseases about the throat partake more or less of the diphtheritic nature, just as certain febrile diseases in a malarious district are often complicated with malaria. Hence, a physician of but a few years of experience, and having observed croup only as it occurs in this city, or in places where diphtheria has at the same time extensively prevailed, would be very likely to conclude that it is simply an extension of the latter disease into the larynx.

Such, therefore, have been the circumstances under which most of these cases have been observed—nearly all of them having occurred since 1875. Cases I., III., V., and XXVIII. present those characteristics which belong to the local disease. The children all died, as I believe, from bronchial croup, without blood poisoning and without infecting others, although there was sufficient time and opportunity for both. Case XX. was pretty clearly one of diphtheritic croup, and yet the boy died as the others had, and also without communicating the disease, although there were several children about him during his entire illness. Case II., at the outset, and until several hours after the operation, presented no symptoms of constitutional disturbance, and yet it terminated as the most terrible case of systemic poisoning of all.

Case XVI. was like pseudo-membranous croup until the last hours of life, and, apparently, infected another child. Now if there be an exudative croup, distinct in its nature and manifestations from diphtheritic croup, a careful observation of these and many other cases has not enabled me to differentiate it either at the outset of the attack or at any time during its progress or after it has terminated. In this dreadful disease "no man can predict what a day will bring forth." What appears to-day as a local, inflammatory disease may, by to-morrow, present the gravest constitutional symptoms.

The microscopical examination of the membrane has not added any differential points. This is more or less well organized, according to the severity of the case and the rapidity with which it is formed, those specimens taken from the trachea and bronchi generally being the toughest and most fibrillated. And this is true of all cases, whether occurring primarily in the larynx or not. In regard to the presence of micrococci, I have found them in all the specimens which I have examined, whether taken from the fauces or air-passages; the more severe the disease the more numerous the organisms. The so-called nests seemed to be nothing more than little lakes and inlets formed by the breaking down and liquefaction of small areas of the purulently infiltrated membrane in which these bodies were crowded. In some cases the membrane peeled off easily and without hemorrhage, and in others the reverse was true. But neither characteristic belonged especially to any particular form of the disease.

Treatment.—The medical treatment of this disease is in the highest degree unsatisfactory. Inasmuch as we know of no medicine which seems to have any influence on the poison of diphtheria, so we cannot expect to accomplish much by internal treatment. "Stimulants and nourishment are our main reliance in the treatment of diphtheria," said Prof. Alonzo Clark, twenty years ago. It was true then and it is equally so to-day, notwithstanding the numerous crops of ephemeral specifics which have sprung up from time to time since then. Medicated sprays and steam, emetics of various kinds, and the internal administration of large and small doses of calomel, have generally failed to dissolve or to dislodge the membrane when located in the air-passages. Individual instances there are of children recovering from grave croup in all stages of the disease and under all forms of treatment, but these instances are so rare and exceptional as to render the efficacy of any given cause of medication exceedingly doubtful. The plan which I should recommend, if the case were seen early, before dangerous and exhausting dyspnœa had set in, would be the following: Apply large, warm poultices over the larynx and reaching two-thirds of the way around the neck. Have them fit as closely as possible, without obstructing circulation or respiration, and changed as often as they become cold. I know, from both observation and experience, that they give comfort, and, at least, temporary relief. Keep the temperature of the room at from 70° to 80° and the atmosphere charged with steam. Use, in addition, if the child can be controlled, the more direct application of steam from some form of croup-kettle, not continuously, but at short intervals of, say, fifteen minutes, five minutes at a time. When the patient is sleeping a gentle stream may be kept up all the time if care be taken not to give it too warm. Many times the children are burned with it from carelessness of the attendants and then cannot be induced to inhale it; but, if carefully managed, they soon learn to appreciate its ameliorative influence over the difficult breathing, and become voluntary assistants in administering it. In a few cases it has seemed to hold the obstruction in check until the disease exhausted itself. Such a one was that of a boy five years old who had a very severe form of naso-pharyngeal diphtheria, with infiltrated cervical glands and cellular tissue, complicated with a nephritis which, at one time, yielded urine containing 30 per cent. albumen and large and small hyaline and epithelial casts. For six successive days and nights the patient had laryngeal obstruction, which, at times, was so severe that I prepared to tracheotomize, but he finally recovered without an operation. He had double vision, paralysis of soft palate and paresis of the lower extremities for several weeks following the attack. Dr. Clark saw him with me in consultation. A frequent repetition of so successful a result, in equally bad cases, would give a specific character to the remedy; but, unfortunately, this is not the case, for, although I have used it quite constantly during the last two years, and have seen it used repeatedly by others, the rule has been that the obstruction progressed to a fatal degree in spite of it. Nor has the substitution of lime vapor seemed to be any more efficacious, whether evolved from slackening lime or projected from a spraying apparatus. Finally, as a last medicinal remedy, some emetic may be given one or two trials, but not more. Of these I consider either the sulphate of copper or the yellow sulphate of mercury as the most prompt and sure. But I cannot too strongly deprecate the custom of repeatedly exhibiting these depressing and exhausting agents in the vain hope that they may ultimately succeed. They only jeopardize the last chance to be given the patient by the operation of tracheotomy.

Tracheotomy.—Premising that the case has been seen early, and that the medical treatment has failed not only to relieve, but also to hold the progress of the disease in check, and that the child is now becoming cyanosed and exhausted, tracheotomy should be performed without further delay. And just here I desire to state, without fear of contradiction by those who have had a large experience in these cases, that there are few operations in surgery attended with more immediate danger to life, or requiring greater coolness on the part of the operator, than that of tracheotomy for croup in young children. Statistics on this point are difficult to obtain. I have personal knowledge, however, of eight children who have died on the table during the operation, and several of them were in the hands of experienced operators. In a certain class of cases it is simple enough; but, when done on a child with thick, infiltrated neck, suffering from profound, systemic poisoning and exhaustion, it becomes an exceedingly difficult and dangerous operation. In order to do it carefully and safely, certain preparations are necessary. 1. Two assistants should be had when practicable. 2. A firm table, covered with an old quilt or blanket, with a pillow placed upon it, should be made ready to receive the child. 3. A hard, cylindrical body, three to four inches in diameter, and six or more inches long (generally an old bottle can be found to answer the purpose best), rolled up in a piece of flannel or other soft cloth, should also be at hand. 4. A small bottle of chloroform, a couple of soft sponges, and two or three large goose-feathers, with well-vaned and flexible tips. 5. Two French double silver canulas, threaded with suitable tapes, a pair of dilators, a couple of retractors, a couple of scalpels, and a sharp-pointed bistoury; a pair of scissors, artery and dressing forceps, a director, threaded needles and ligatures, should be within reach of the operator or his assistant. 6. A basin of water in which to cleanse the sponges or other things. While these preparations are being made, the child should be given a teaspoonful or two of brandy. Now place the child on the table, with the pillow under its head, having previously unclothed the neck and chest, and let chloroform be carefully, but not timidly, given by the most experienced of the assistants. As soon as sensibility is lost, the bottle, or other body used, should replace the pillow by being put under the back of the neck, well against the shoulders, so as to throw the head back and bring the trachea forward and superficial as far as possible. See that the body and neck of the child are in line, and kept so. Standing on the right side of the child, make the primary incision in the median line, beginning at the lower border of the thyroid cartilage, and extending it to within half an inch of the sternal notch.

Having divided the skin and superficial cellular tissue, a nick in the deep fascia will enable the operator to pass a director under this tissue, and it should be done, and this and all the subsequent layers divided on the director whenever the knife is used, except little touches now and then which can be made with perfect safety. The best guides to the median line, which should always be kept, are the sterno-hyoid and sterno-thyroid muscles—especially the latter, whose whitish and firm inter-muscular fascia can generally be easily distinguished. In addition to these aids, the left index finger can, from time to time, be introduced into the wound and the trachea felt, so as to make sure of its relations. After the division of the deep fascia, the thyroid veins are seen ramifying in the deep subcellular tissue, often large and numerous, and lying more or less in the track of the incision. Now, it is better to take the scalpel-handle or director, or both, and cautiously tear away the cellular tissue from the median line, taking care to avoid the veins and to draw them aside when necessary. Much aid will be afforded to the deeper dissections by having the assistants hold apart the edges of the parts already divided, with the retractors. Often, after the deep fascia is opened, the remaining layers covering the trachea can be torn away with the handle of the knife or with the fingers. Sometimes the trachea lies very deep, and the wound, which was long enough at the outset, is allowed to get shorter and shorter in the deeper dissections, until, when the trachea is reached, it is found that there is not sufficient of the latter exposed for the necessary opening. In that case, unless the deeper cut can be lengthened without danger of wounding the vessels, it will be better to begin superficially at either the upper or lower angle of the incision and divide the tissues again, layer by layer, as extensively as necessary. Having clearly exposed the trachea to a sufficient extent, say half an inch, the soft parts should be held away with the retractors, being careful not to pull too hard on them lest the trachea be flattened, and thereby not only respiration impeded, but the posterior tracheal wall endangered when the opening is made. Now, having the dilators and one of the tubes where they can be immediately picked up, with the sharp-pointed bistoury open the trachea (preferably just below the isthmus of the thyroid), cutting either from below upward or from above downward, it matters little which, if carefully done. The eye is the best guide as to how large this opening should be, but it is better to make it too small than too large at first, for it can easily be enlarged subsequently. Great care should be used also not to thrust the point in too far. It will be felt free as soon as it has perforated the anterior wall. Usually, as soon as the wind-pipe is punctured, the fact is announced by the hissing of the air as it rushes in through the opening. Occasionally the respiration is for the moment suspended, and no sound is emitted. The dilators should be introduced as soon as the opening is made. A violent cough, with the expulsion of large quantities of pus, blood, and sometimes membrane, immediately ensues. These matters should be caught with a sponge as they appear, and not allowed to be sucked back into the bronchi. As soon as the convulsive coughing subsides, the inner surface of the trachea, as far as can be seen through the opening, should be examined for membrane. If any is seen that can be removed with forceps or by other means, it is better to remove it. In some cases it may not be practicable to delay introducing the tube after the trachea is opened; but generally, if the child's breathing be safe and hemorrhage not troublesome, there is no hurry, since the dilators keep the wound open and admit plenty of air, and the way can be made clear before putting in the canula. As soon as this is done, the chloroform should be withheld, the tapes fastened, and the wound stitched while the child is recovering consciousness. It is better not to close the edges of the soft parts tightly around the tubes, but to leave a little space above and below of a quarter of an inch or more, so that its movements may be free, and also to avoid the tendency to emphysema of the neighboring cellular tissue, especially if the tracheal opening be large. A quiet sleep of one or more hours usually follows the operation, and during this period it is just as well to let the patient remain on the table, taking care to make him comfortable with pillow and covering, and having some competent person sitting by with a moist sponge, ready to sop up the secretions as they are coughed up from time to time through the tube.

The following method of operating is practised by my friend, Dr. John J. Reid: "The operation consists in making the usual incision in the middle of the neck and dissecting up the skin. The strong superficial fascia in the median line which connects the sterno-hyoid muscles is then separated, and subsequently the knife is dispensed with till it becomes necessary to incise the trachea. The remaining part of the operation is performed by two tenacula, and consists in tearing the deeper fascia and drawing the thyroid veins to either side in such a manner that the trachea is thoroughly denuded. To such an extent may this be done that the whole of the trachea, from the cricoid cartilage to the thymus gland, may be separated from the thyroid gland and veins, and leave a free surface for incision. After the operation has proceeded thus far, a tenaculum is inserted into either side of the trachea, and slight traction made. A bistoury is then carried through the rings, when immediately the trachea bulges open and is so maintained by the tenacula." There are several points connected with this operation which, I believe, should be considered more particularly.

1. The question of anæsthetics. I have twice seen the operation performed on a conscious, struggling child, and I do not wish to add to that experience. If the child be sufficiently conscious to suffer pain and to struggle, I believe it is both safer and more humane to give an anæsthetic; and, if the choice is left to me, I much prefer chloroform. In my opinion it is at least equally as safe as ether in these cases, more rapid in its action, while its effects are less prolonged, and it is less disagreeable to inhale and less likely to be followed by depressing nausea. Besides, what I consider very important, it almost always has a tendency to relieve the dyspnœa while being inhaled, whereas ether, especially at the beginning, has the opposite effect. If it be dangerous to give these toxæmic children, with feeble hearts, chloroform, would it not be quite as dangerous to allow them to struggle and suffer pain and fright during the operation, to say nothing of the additional risk of accidents? Of course, it is of the most vital importance to have a competent administrator.

2. The *dilator*, as Trousseau has truly said, is indispensable. It is easily introduced, and it not only makes the introduction of the tube into the trachea a simple procedure, but it enables the operator to examine thoroughly the interior of the windpipe in the neighborhood of the wound, and to extract any visible false membranes before fixing the canula in place. Various forms of this instrument are in use, but the most satisfactory is that which bears the name of Hutchinson. It is bivalvular, with slender blades, slightly clubbed at the extremities. Trousseau's instrument is not quite so easy of introduction, but preferable to any of the others that I have seen.

3. The question as to the form and size of *canula* to be preferred is an important one. In my opinion the best form is the double silver tube with movable plate. As to size, although I have sometimes used larger, I have found that one the diameter of whose outer rim is about five-sixteenths of an inch is sufficiently large for any child, while it has twice served for a child under one year of age. And, *per contra*, I have twice had it in an adult with occluded larynx, and found it supplied all the air required. The objection to using one much smaller, even for a very young infant, would be that where the calibre is very small it becomes easily occluded. Still, I have used one successfully whose diameter was only three-sixteenths of an inch. The *length* required is not ordinarily more than two to two and a quarter inches, unless the neck be much swollen. Again, the tube should not be too much curved, otherwise it endangers the anterior tracheal wall by its pressure, does not admit air as freely, and gives the patient pain.

In short, a tube should be perfectly movable both outside and inside the trachea. The hard rubber instruments are objectionable on account of their brittleness and the relatively small size of the lumen as compared with their diameter.

When one has been introduced suitable to the case, it fulfils all the indications for which it was devised, and better than any other invention that I know of. It is painless, non-irritating to the parts, not easily displaced, and keeps the way open as far as it reaches.

Accidents and complications during the operation.—1. Hemorrhage to any alarming degree usually arises from the unintentional division of one or more of the deep cervical veins. By careful, deliberate dissection it can generally be avoided, and, in a majority of cases, there is time for this painstaking. If, however, it occur, it should at once be arrested by ligaturing the bleeding vessel, unless asphyxia be extreme. Holmes, in his excellent article on tracheotomy ("Surg. Dis. of Children"), speaks of the danger of wounding the innominate artery in low operations, when that vessel crosses the trachea at an unusually high point, and quotes a case in which this accident actually occurred. In two of my own cases I fully exposed this artery, and, had I not been carefully dissecting, might have injured it. In both instances the children were under two years of age, and the vessel abnormally high in the neck. 2. Cessation of respiration sometimes occurs suddenly, either during the operation or just after the tube is inserted. In the first instance, if it does not begin again after withholding the chloroform and giving the child a few shakes, the head should be lowered a foot or more below the level of the hips by raising the foot of the table, and artificial respiration resorted to. Frequently, the change of position alone will succeed. The resting, as it were, of the respiratory muscles after their terrible labor which sometimes succeeds the introduction of the tube, must not be mistaken for that paralytic condition characterized by blanched face, dilated pupils, and feeble or absent pulse. In the one case there are no consequential symptoms, and, if closely observed, it will be seen that there is some slight respiratory movements. It needs no treatment. In the other, one of the most successful plans is to pass one of the feathers down through the tube and irritate the tracheal mucous membrane. This failing, lowering of the head and artificial respiration should be faithfully tried. 3. Difficulty of introducing the tube is occasionally met with. If the trachea be well exposed before being opened, the dilators introduced as soon as the opening is made, and the retractors held in position until the tube has been inserted, this complication will not often arise. If the opening become displaced and lost sight of in attempting to get the canula in, and the symptoms be not too urgent, search should be made for it before incising the trachea a second time, although I have no reason for supposing that a second incision would imperil the result. The dilators sometimes stretch and flatten the trachea, or do not open sufficiently wide to admit the trachea tube between the blades, because the set-screw has not been properly fixed beforehand. Sometimes the blades are pushed down too far into the windpipe, and hence the difficulty of passing the canula. Displacement of the prop under the neck is another cause. With proper precautions I do not see how the tube can be mistakenly pushed into the cellular tissue in front of the trachea, unless the operator become very much confused. In any event, if air does not pass through the tube, it should at once be taken out and the explanation sought for, no matter how serious the difficulty of replacing it.

4. Mediastinal emphysema. In a certain proportion of cases, in which the neck is short and thick, and the difficulty of reaching the trachea thereby increased, the anterior mediastinum may be opened and air sucked in during the operation. This ceases, if not before, as soon as the trachea is opened and the cause of the vacuum removed. I have shown the result of this in one of the autopsies. It probably does little harm and would soon disappear if life were prolonged, as it does in the superficial cellular tissue when the cause is removed.

After-treatment.—How great an amount of time is necessary in the management of these cases during the first few days following the operation, if we would hope for success, can only be realized after personal clinical experience. They should be seen at least every eight hours, and there are almost always little things to do at these visits which consume time. The mute, helpless condition of these little ones excites our sympathies, too, and we linger about their cribs, lest something be left undone which might add to their comfort or improve their chances of recovery. But, in spite of our best efforts, a very large majority die, sometimes more painfully than if we had abandoned them to their fate before doing tracheotomy; and, in such cases, the only consolation is that we tried to do our duty. Usually, during the first twenty-four hours, the case progresses favorably, and everybody is thankful. If the breathing is perfectly free, a large, moist sponge may be fastened over the mouth of the tube by attaching strings to its extremities and carrying them around the neck behind and tying them. This is a much better arrangement than Trousseau's cravat, which is soon saturated with the secretions, gets dry and stiff and foul-smelling, and, if not watched closely, adheres to the tube-plate and becomes a source of obstruction. The sponge accomplishes the double purpose of warming and moistening the air to be inspired just as well as the cravat, can be easily kept clean, and need only to be raised a little in order to manipulate the tubes. If the breathing be at all harsh the direct inhalation of steam from the croup-kettle should be kept up. Whatever the condition of the child, I think it is better to keep the atmosphere of the room moist, by means of kettles of boiling water in which, if necessary, may be placed certain articles of bedlinen or clothing. An equable temperature of between 70° and 80°, regulated by a thermometer, should be maintained. The inner tube should be taken out and cleaned as often as it becomes obstructed, but not on the occurrence of every little rattle of mucus. On the second day it will be well to remove both tubes and clean them thoroughly and apply new tapes. At the same time the wound can be cleaned and the permeability of the larynx tested. A washer made of several thicknesses of muslin, oiled-silk, or other suitable material, and smeared over with a bland ointment, when placed between the plate and the wound, adds comfort to the patient. If the first tube be of proper size and length, I cannot see that it is necessary to change it.

If the swelling of the parts diminish, making it too long, or the reverse occur, making it too short, or if it press injuriously at any point, substitute another. But, if adults can wear the same tube for months, I do not see why children cannot for days or weeks. The wound does not need any special treatment other than that suggested above, unless extensive cellulitis or emphysema occur. It is common to have the wound covered with membrane, and I think it should be treated as the majority of practitioners treat membrane on the tonsils—let it alone. If cellulitis be extensive and severe, hot poultices are indicated, after cutting the stitches loose. When the tube is properly in the cavity of the trachea, the subsequent occurrence of emphysema will be rare unless the tracheal incision has been much too long, and the wound closed too tightly around the canula; in that case, each expiration of violence forces air into the cellular tissue through the opening between the angle of the wound and the tube. This has never happened to me but once, and that was in the case of an adult. Cutting loose a couple of stitches relieved the cause, and the effect disappeared in a couple of days. Erysipelas, starting in the wound and extending more or less over the neck and chest, cannot be checked by local treatment. For want of something more efficacious, I still use the muriate of iron internally. I cannot see that removing the tube would accomplish anything, even if such a procedure were safe, although it is recommended by Cohen; for, at this period of the case, the tube usually hangs loose in the trachea, neither the plate nor the tapes coming in contact with the wound, which can as easily be kept clean as when the instrument is out. Hemorrhages occurring in consequence of abrasions or ulcerations of the mucous membrane of the trachea have not proved sufficiently alarming, in my experience, to demand any other treatment than the careful avoidance of disturbing the parts by changing tubes, passing probangs, etc. If I had a case in which the hemorrhage was profuse and persistent despite the application of styptics by means of a bit of sponge fastened to a pair of curved forceps, I should resort to Trendelenburg's obturator, as suggested to me by Dr. McBride. If there be nasal diphtheria, producing a sanious, irritating discharge, the parts should be kept as clean as possible by wiping the nose and upper lip with a silk handkerchief or a soft moist sponge occasionally. Since the respiration is carried on through the opened trachea, it is unnecessary to syringe out the nasal passages with a solution of salt and water, as is sometimes indicated *previous* to the operation, especially in those cases in which the pharynx and fauces are very much swollen, and we wish to keep open all the avenues for the admission of air. Although nasal diphtheria is sometimes associated with the graver forms of the constitutional infection, it is quite as often, in my experience, found in mild cases. Nor is there any more constant relation between nasal diphtheria and infiltration of the cervical glands. Severe cases have swollen cervical glands, whether the nasal passages are involved or not, as a rule, and very mild cases do not, even though the nares be involved.

Any theory based on the real or supposed anatomical relation of the absorbents of these parts must bear the test of clinical observation, or fail, no matter how plausible it may be. Inflammations and ulcerations of the nasal cavities exist for months and even years without markedly involving the cervical glands, whether the causes are scrofulous, specific, or malignant. Of course, in many cases of ozæna and chronic catarrh, all the lymphatics are more or less involved because the disease is of scrofulous origin. In what form or by what avenue the diphtheritic poison first enters the system is not known. But it is known that children sometimes suffer for days from severe constitutional symptoms, while the most careful search fails to discover any true local manifestation until later. In fact, the rule is, where intelligent, close observation has been made, that constitutional symptoms precede local. Neither is it at all necessary that the first localization be in the throat or nose; many cases have been observed in which the first deposit was as far removed as possible from these parts. There is no constant relation between the local and constitutional manifestations. Some patients being struck down, overwhelmed with the poison, and dying before any considerable deposit of membrane or any marked inflammatory changes have, as it were, had time to take place in the fauces; and, on the contrary, nares, fauces, and pharynx may be covered with membrane and yet the constitutional disturbance be slight. Jacobi said in 1860: "Diphtheria is a general disease; it has local deposits, it is true, but in the same manner that scarlatina will localize itself on the skin, mucous membrane of the Bellinian canals, etc; measles on the skin and the mucous membrane of the respiratory organs; or typhoid fever on the mucous membrane of the intestinal tract" (*American Medical Times*, vol. i., p. 95). This is a clear, perspicuous, and, I believe, true statement. Hence the folly of expecting to cure the disease by any local application; or of trying to prevent auto-infection in a system already charged with the poison. One might as well attempt to cure small-pox by frequently washing the pustules with a "disinfectant." But, even on the theory that these children die of septicæmia, and that the poison is absorbed from the nasal cavities, which seems very improbable, is syringing out these cavities several times an hour, as advocated by some authorities, indicated? Who thinks of washing out an infected uterus, or abscess of the pleural cavity or other organ, with any such frequency? If carried out as recommended, it must prove a most exhausting plan of treatment.

(To be continued.)

A Home Hospital, which admits patients and allows them to continue under the care of their family physician, has been opened in London. It is somewhat on the plan of the French Maison de Santé, and is a kind of institution much needed in this country.

THE CONTAGION OF CONSUMPTION.

By JAMES T. WHITTAKER, M.D.,

PROFESSOR THEORY AND PRACTICE OF MEDICINE, MEDICAL COLLEGE OF OHIO.

The most important question now engaging the attention of the medical world is the contagion or the communicability of consumption. Clinicians here and there, have from time immemorial held the view that consumption was contagious. The authorities, from age to age, who have made themselves such by the close study of the disease, have died of it. Such was the fate of Bayle, Young, Laennec, and many others. Riverius made the observation as long ago as 1668, that members of a family have one after another succumbed to the disease. Contagion he declares to be the "chiefest" cause of phthisis; "for this disease is infectious. We may observe women to be infected by their husbands and men by their wives, and all the children to die of the same, not only from infection of their parent's seed, but from the company of him that was first infected." Similar observations have been made in every decade since, and yet any general acceptance of the infectiousness of phthisis never obtained until the disease was inoculated in lower animals, first of all 200 years later by Villemin, 1865. The value of experimentation on the lower animals has never been so conclusively demonstrated as by the confirmation thus afforded of the specificity of the tuberculous virus.

It is worth while, however, to notice the force of the convictions of some of the clinicians from mere bedside observations.

Before his death, nearly fifteen years ago, Budd, one of the shrewdest clinicians who ever lived, wrote:

"The following are the principal conclusions to which I have been led regarding phthisis or tubercle—

"*First.*—That tubercle is a true zymotic disease, of specific nature, in the same sense as typhoid fever, scarlet fever, typhus, syphilis, etc., are.

"*Second.*—That, like these diseases, tubercle never originates spontaneously, but is perpetuated solely by the law of continuous succession.

"*Third.*—That the tuberculous matter itself is (or includes) the specific morbific matter of the disease, and constitutes the material by which phthisis is propagated from one person to another, and disseminated through society.

"*Fourth.*—That the deposits of this matter are therefore of the nature of an eruption, and bear the same relation to the disease, phthisis, as the yellow matter (the stools), for instance, of typhoid fever.

"*Fifth.*—That by the destruction of this matter on its issue from the body by means of proper chemicals, or otherwise, seconded by good sanitary conditions, there is reason to hope that we may eventually, and possibly at no very distant time, rid ourselves entirely of this fatal scourge."—*The London Lancet*, Oct., 1867.

Dr. W. H. Webb, of Philadelphia (who entertained the idea "which came into his head unbidden, so to speak, while walking on Observatory Hill near Clifton, in the second week of August, 1856"), in a paper, "Is Phthisis Pulmonalis Contagious, and does it belong to the Zymotic Group?" read before the Sydenham Medical Coterie of that city in 1878, quotes from Hippocrates, Galen, Riverius, Morton, Van Swieten, Baume, Cullen, Heberden, E. Darwin, Goode, S. G. Morton, Bright and Addison, Laennec, Hastings, Drake, Walshe, Copland, J. Frank, Hufeland, and Hildebrand, in support of this view. Dr.

E. Holden, in the same year, in response to inquiries addressed to 250 leading physicians of the United States, obtained from 126 an expression of belief in the communicability of consumption. Yet, notwithstanding this array of authority, physicians generally are so little convinced of the infectiousness of tuberculosis as to experience and express surprise when the statement is made anew from time to time.

What has especially prevented the general acceptance of the infectiousness of tuberculosis is the widespread belief in the almost exclusively hereditary transmission of the disease. Of this transmissibility there is no shadow of doubt, but, fortunately for the human race, heredity does not account for even the majority of cases. Because members of the same family succumb to the disease, is not so much proof of the influence of heredity as of contagion, for a like implication is seen in all kinds of infectious disease among individuals in close association. And it is the observation of every practitioner of experience that a large contingent of cases develop entirely independent of heredity. To invoke the possible existence of the disease in the remote ancestry or distant relationship is a safe refuge, of course, because no generation escapes in all its members; but such an explanation savors too strongly of the metaphysics of the middle ages to satisfy the more accurate demands of modern times. That phthisis is acquired oftener than inherited is a fact which becomes more patent every day.

The pathologists finally reached the same conclusion in the slow evolution of their investigations. At first consumption was an ulceration of the lungs. Then solid masses were encountered, nodules or tubercles. The nodules were observed to be of smaller and smaller size, even down to granules. So, Hippocrates and Galen speak of ulcerations and suppurations. Sylvius, 1640, first found the nodules which he believed to be pulmonary glands. Bonnet, 1679, speaks of small tubercles which Mangetus, 1700, compared to millet-seeds. Baillie, 1793, distinguished tubercles from pulmonary glands, and Bayle, 1810, recognized them as developed independent of ordinary inflammations. Laennec, 1810, shows that the different kinds of tubercle, which are new formations, represent different ages of the same products. "The recent progress of anatomy," he says ("De l'auscultation médiate," etc., p. 10), "has shown that these cavities are due to the softening and consecutive evacuation of a *particular kind of accidental production* (italics ours), to which modern anatomists have applied especially the name of *tubercle*, a term used in general, hitherto, for every kind of tumor or abnormal protuberance." Rokitansky, 1842, like Louis before him, adopted the view of Laennec, that tubercles are neoplasms, and are consequently specific and, *sui generis*, a support, as Ruehle remarks, which "seemed to at last definitely prove the specific nature of phthisis."

Such was the prevailing doctrine regarding tuberculosis up to the time of Virchow, 1847. This distinguished pathologist claimed to demonstrate the development of tuberculosis from any caseous matter, and caseous matter in turn from any necrobiosis of tissue. The view so clearly presented by Carswell, 1813, that consumption might result from any ordinary inflammation was thus reinstated, and at the hands of Niemeyer, 1867, a clinician of the cellular pathology school, so plausibly elaborated as to set back the specificity of tuberculosis for several decades. According to Niemeyer a catarrhal pneumonia developing in a healthy constitution has its effused products undergo fatty degeneration and absorption, with resolution of the disease; but, developing in a so-called "vulnerable" constitution, the inflammatory products undergo caseous degeneration and remain. The disease is now known as caseous pneumonia (phthisis). The absorption of the caseous matter in turn produces a peculiar blood-poisoning which is known as tuberculosis. So, tuberculosis was a tertiary factor incident to the absorption of caseous matter, itself a secondary factor incident to a catarrhal inflammation in a vulnerable constitution. These conclusions, as consecutively put as the chain of catastrophes in the house that Jack built, passed into general favor at once and were quoted on every hand. But they were fatal to any further progress in the domain of tuberculosis. A tuberculous patient was doomed from the start, because he had already in his original construction a "vulnerable constitution," and he was hurt in the vulnerable part.

As might be well imagined, clinicians generally could not rest content with this gloomy outlook upon a disease which destroys, according to Hirsch, two-sevenths of mankind. We may, therefore, readily appreciate the thrill which was occasioned everywhere by the first experiments of Villemin in 1865, demonstrating that tuberculosis, in any of its products, was inoculable. Tuberculous matter introduced beneath the skin of a rabbit or guinea-pig produced tuberculosis. So-called control experiments were generally instituted at the hands of numerous observers. From these experiments it seemed to be proven, first, that the disease thus induced in lower animals was not the tuberculosis of man; second, that other noxious agents, like decomposing meat, or even innocuous substances, like elder pith or india rubber, would produce the same symptoms; and, third, that the so-called tuberculosis thus induced was the result simply of the absorption of caseous matter produced in any way. The death-blow seemed thus to have been dealt to the infection theory, and the therapy of tuberculosis was left in the same deplorable state as before. It remained now only for the pathologists, as a question of purely scientific interest, to develop caseous matter in the lungs. Given the caseous matter and the problem of tuberculosis was solved. Soon it came to be observed, however, that croupous pneumonia, that is, our so-called frank pneumonia—in our nomenclature lobar pneumonia—never terminated in caseous degeneration. Since the publication of the remarkable paper by Juergensen, lobar pneumonia, far from being a frank, typical inflammatory disease, has become an acute infectious disease of cyclical course, with a crisis, a typical temperature curve, and a definite duration. Croupous pneumonia had therefore to be ruled out of the etiology of tuberculosis. Next it was seen that catarrhal pneumonia, our lobular pneumonia, or sometimes our capillary bronchitis, seldom or never furnished the desired caseous matter for further infection. So it was left then for Buhl to invent or discover a new form of pneumonia, to wit, the desquamative pneumonia, whose object it was apparently to develop the caseous matter.

The subject of tuberculosis stood now about as follows: According to the views of the pathologists, with Buhl at the head, phthisis or tuberculosis was a resorptive disease. It resulted from the absorption into the blood of caseous matter. This resorption might occur at any time, and when it did occur, it was necessarily fatal in its effects. According to the clinicians, with Niemeyer at the head, there was no therapy for the disease beyond a general building up of the body, including everything that is meant by a more perfect hygiene. Bad air and bad food, bad sewage, overcrowding, any defective hygiene, might cause the disease, and the only hope for mankind lay in sanitation.

So phthisis was a disease without a therapy. Symptoms might be met and prostration relieved for the time being, but there was no future for the victim of the disease. True, clinicians had occasionally observed that most individuals recover from the disease; that post-mortem examinations upon individuals dead from other affections, or killed by accident, showed the presence of encysted or degenerated tubercles at the apices of the lungs, sometimes unsuspected during life; that it was exceptional, in fact, to find lungs free from all tuberculous deposit. The view now began to prevail that phthisis was a self-limited disease; it might run a definite course, of indefinite duration, and then be expelled from the body, provided the body could be in the mean time sustained.

Some inexplicable cases of basilar meningitis began to be observed. For the most part, brain tuberculosis had been considered as a typical illustration of the heredity of the disease. In every case, or in every suspected case, the practitioner would make anxious inquiry regarding ancestral phthisis. But cases were encountered where no such antecedence appeared. Thus, Reid reported ten cases in the *Berlin. Wochenschrift*, Sept. 18, 1878, to all of which the disease had been clearly communicated by a phthisical midwife, who subsequently died of the disease, and in none of which could there be traced any history of hereditary phthisis. Tubercular meningitis, like bone tuberculosis, had hitherto been regarded as an invincible argument against any reception of the disease from without, and the occurrence of cases of either among individuals free of its inheritance constituted a stumbling block in the pathology of the disease, which could only be surmounted by the theory that tuberculosis might result from any ordinary catarrhal or traumatic inflammation. A little later came the observation of Tappeiner, to the effect that dogs shut up in a box whose air was impregnated with atomized phthisical sputa, inevitably died of the disease. Jacobi had long ago reported the case of a dog who had died of tuberculosis from eating the sputa of his phthisical master, and occasional cases of like import have found their way into medical journals from time to time since, the last in a recent number of the *British Medical Journal*. Here was now a new insight into the nature of tuberculosis. Cohnheim and Solomonsen now made their famous experiments upon rabbits, and found that tuberculous matter introduced into the eye or other organ invariably produced first local and afterward general tuberculosis, and that tuberculosis could be produced in no other way. What made these experiments especially valuable was the fact that they were undertaken in the spirit of scepticism. For Cohnheim was himself the most authoritative opponent of the specificity of tuberculous virus when the theory was first promulgated by Villemin. Cohnheim found that the introduction of the smallest particle of tuberculous matter through a lineal incision into the eye of a rabbit was followed, after a period of incubation of about six weeks, by an eruption upon the iris of minute nodules "which increase to a certain size, and then undergo caseous degeneration, to be followed, in turn, in the course of months, by a more or less general tuberculosis of the lungs, peritoneum, and various other organs." Cohnheim is so convinced of the inoculability of the virus that he proposes to utilize it as a diagnostic criterion of tuberculous products. We are unable, he says, to differentiate tuberculous matter with certainty in any other way. "Neither the nodular form, the histological structure, the occurrence of giant cells, caseation, nor all these circumstances together, are absolutely characteristic of tuberculosis. *The only absolutely perfect and certain criterion is the capacity of infection.*" The products of local tuberculosis are just as inoculable as those of general tuberculosis, hence the disease process is essentially the same. Phthisis pulmonalis is a local tuberculosis. The ingestion of its products, or the ingestion of tuberculous virus with the food, as in the milk of tuberculous cows, begets intestinal tuberculosis. Scrofula is a more or less local tuberculosis, the virus being still confined to the lymph glands in the vicinity of the place of its absorption. The caseous swellings of the cervical lymph-glands are thus explained. According to Weigert, the virus may reach the brain by inspiration through the cribriform plate of the ethmoid bone, and thus induce basilar meningitis first. Primary bone and joint tuberculosis presuppose the existence of the virus in the blood, and the extravasation of it in greater quantity at the affected regions. The implication of the pulmonary veins or thoracic duct—conditions encountered in post-mortem examinations of such cases—lead to a profuse inundation of the juicy organs with tuberculous virus, and account for the cases of rapid and universal dissemination, the cases of so-called acute miliary tuberculosis.

The whole question of the contagion of consumption, *i. e.*, of the specificity of the tuberculous virus, hinges upon its inoculability, and of this capability there is now scarcely room for doubt. Harnsell (Graefe's *Archiv.*, 25, part iv., 1879) mentions cases of tuberculosis iridis, as reported by Perls, Manfredi, Koester, Leber, Samelsohn, Sattler, and Angelucci, and adds three cases from his own (Göttingen) clinic. He thus establishes the fact of infection of the iris. After mentioning the experiments of others in direct and indirect inoculation of the eye with tuberculous matter, the author then proceeds to detail his own. He found that the insertion of tuberculous matter into the anterior chamber of the eye invariably inoculated the iris. The cornea and conjunctiva, moreover, could be inoculated directly, and in all cases the tuberculous matter inserted "disappeared by the third day, and after from fifteen to twenty-three days of incubation tuberculous collections showed themselves."

The fact that these collections or masses were tubercular was proven after the method of the chemists in recognition of the action of a poison, that is, by insertion into the bodies of other animals. Particles or portions were put into the abdominal cavities of dogs and guinea-pigs. The dogs died of suppurative peritonitis. The guinea-pigs were kept under observation for three months and then killed, when "all the internal organs and the skin were found, without exception, to be filled with deposits of miliary tubercles." Cohnheim tried in vain to excite tubercles in the iris "by introducing into the anterior chamber portions of non-tuberculous animal tissues of the most varied kind," and Harnsell failed to inoculate tuberculosis with fresh trachomatous matter. "On the other hand, the tuberculous matter used, when introduced into the peritoneal cavity, excited, in turn, general tuberculosis of all the organs."

"*So in tuberculosis,*" as Cohnheim concludes, "*everything depends upon the virus. We discover at all points the closest analogies between tuberculosis and syphilis. Both require, above all things, infection, transmissibility of the disease from person to person.*"

This comparison between tuberculosis and syphilis is exceedingly happy. The conduct of no other infectious disease so closely resembles that of tuberculosis, or so completely clears up the perplexities which beset the disease. To compare tuberculosis with small-pox, for instance, would be fatal to our understanding of either, while tuberculosis and syphilis present so many analogies as to have even led some pathologists to regard one as a form or a product of the other, a conception which is, of course, radically wrong.

Tuberculosis, like syphilis, depends then upon a specific virus which must reach a mucous membrane or a broken surface, to be absorbed and induce the disease. Laennec was convinced that he had inoculated himself once with tuberculosis, just as many an unfortunate practitioner has since inoculated himself with syphilis, by a wound from a saw in making a post-mortem examination upon a phthisical patient. But more fortunate than they, he succeeded in destroying the tuberculous nodule at the start with the butter of antimony.

Syphilis, for the most part, reaches the body through the organs of generation, while tuberculosis is breathed, for the most part, into the lungs, or is swallowed with food, as with milk, the most frequent cause of tuberculosis in childhood.

The first symptoms of each affection are local; in syphilis, at the genital organs, in tuberculosis, at the lungs or in the intestinal canal. From the point of absorption the disease next invades the lymph glands in the nearest vicinity; in syphilis, the glands in the groin, in tuberculosis, the bronchial and mesenteric glands. Passing these glands, or being absorbed into the blood, both diseases become general.

Both diseases may be transmitted by heredity, and both diseases, thus transmitted, may lie latent for a time, for a longer time in tuberculosis, to develop at a later period. During the latent stages, both diseases impair the processes of nutrition, and deform the development of the body. The victim of latent syphilis has notched teeth, falling hair, derangements of digestion, etc. The victim of tuberculosis shows the aspect of scrofula, or has the sunken, elongated chest, ossified ribs, the thorax paralytica; he has also clubbed fingers, and the other well known signs which constitute the *phthisical habitus.* This habitus is therefore an effect and not an inviting cause of the disease. An individual thus affected is said to have the tuberculous diathesis, just as an individual once syphilized has the syphilitic diathesis. Either disease may manifest itself in its well known symptoms at any time. But latent or manifest, the disease is present, just the same. all the time.

There is, then, no such thing as a predisposition to either disease. Either a man has syphilis or he has it not. Either a man has tuberculosis or he has it not. One man is not more predisposed to either disease than another. Syphilis affects one individual more than another, because its virus finds a better lodgment upon his mucous membranes. Tuberculosis finds also, fortuitously, a better nidus in one case than another. The virus of tuberculosis is lodged in one case and not coughed up, just as in syphilis the virus is secreted and not washed off.

Both diseases may disappear from the body entirely, and a perfect cure may result, but it is impossible to state when such complete eradication has taken place. In syphilis the capability of reinoculation furnishes the only definite information in this regard, a method of trial not so likely to be undertaken in tuberculosis. As a rule, however, neither disease does disappear from the body entirely. What Fournier said of syphilis is true also of tuberculosis, viz., that the diathesis is a period of health interrupted by explosions of the disease. Cazenave said long ago that one does not recover from the syphilitic diathesis, but lives with it as with the lymphatic temperament, and an older writer observed that syphilis strikes with its victims "a truce oftener than a peace."

Both diseases may, and for the most part do leave in the body centres of future infection. From any chancre, plaque, gumma, or other deposit of syphilis, reabsorption may take place at any time, and reinfection with syphilis, or, better, reappearance of external signs. So, from any caseous nodule wherein the tuberculous virus is locked up in temporary innocence, absorption may take place under favoring circumstances and a new outbreak of tuberculous symptoms appear, the quantity of the virus thus set free, determining to great extent, perhaps, the virulence of the symptoms. While the virus is thus locked up the disease is latent, when set free, it is manifest.

While it is true, therefore, of both diseases that they may be inherited, that is, that both syphilis and tuberculosis may affect the ova and spermatozoids as well as every other organ and tissue of the body, it is also true of both diseases that they are in the vast majority of cases not inherited, but acquired. A thorough sifting of the cases will show this statement to be as notoriously true of tuberculosis as of syphilis. So soon as the inoculability of tuberculosis is established, the fact is also established that the disease is acquired oftener than inherited.

With the general recognition of these views, we shall cease to hear of bad air and bad sanitation as direct factors in the disease. The writer of this article once went so far as to develop tuberculosis from depressing mental emotions. Bad air, food or drink, are productive of tuberculosis only when they contain the virus of the disease. In other respects they are no worse for tuberculosis than for any other disease. Drinking water contaminated with sewage does not produce typhoid fever unless the sewage contain the typhoid germ. So, contaminated air is productive of tuberculosis only when a cause of its contamination is tuberculous virus. Drs. Cotton and Edwards, of the Brompton Hospital for Consumptives, object to the contagiousness of consumption on the ground that but one nurse and one servant died of phthisis in that institution in a period of twenty-one years. Dr. Cotton went so far as to say that "a residence in the consumptive hospital and long continued working in its wards is a very good way, indeed, *not to catch the disease.*" It must be remembered, however, that few institutions were in such perfect sanitation, especially as regards ventilation, as Brompton Hospital. Anyhow, the statement does not count for much else than to show how close an association is necessary to contract the disease. For the same observation has been made with reference to typhoid fever, an infectious disease beyond a doubt. Liebermeister states that up to the year 1865 he had never seen in the hospitals which he visited (Greifswald, Berlin, Tübingen), "a single hospital patient, physician or nurse, attacked with typhoid fever, although such cases are placed in the general wards. And the same author quotes from Murchison to the effect that "during a period of fourteen and a half years in the London Fever Hospital, 2.506 patients were treated with typhoid fever, and during that time only eight cases originated in the hospital."

The specificity of the tuberculous virus is determined in a higher school, and by means more in accord with the principles of science than clinical observation. And the recognition of it clears the field for prophylaxis and opens up a new and more promising outlook for the therapy of the disease.

CONVERGENT SQUINT.

Cause, Results, and Treatment.

By C. A. BUCKLIN, M.D.,
SURGEON TO THE NEW YORK EYE, EAR, AND THROAT INSTITUTE.

(Continued from the MEDICAL RECORD, No. 21, Vol. xvii.)

THE cause of "77 per cent." (Donders) of all cases of convergent squint has been explained. We will now give our attention to cases of squint where refractive errors are not the cause, then pass to cases of *convergent* squint which are sometimes associated with, and dependent upon, myopia (near-sightedness). A person who, from an injury or other cause, has one muscle inflamed and contracted (be the vision good or bad) presents the same muscular condition as one who has simple hyperopic squint.

In the first case, the contraction of the muscle deviates the eye when at rest. If the muscle still preserves its natural contractility, the normal amount of inervation necessary to produce the usual accommodation and associated convergence for near objects will increase the deviation of the eye inward exactly as in hyperopic squint.

In hyperopic squint the eye is deviated inward at first by an abnormal inervation of the internal rectus for the purpose of obtaining distinct vision in the fellow eye, as already described.

In the other case, the increased deviation of the squinting eye has no effect on the amount of accommodation in the fixing eye, or. on the other hand, the amount of accommodation required in the fixing eye would not necessitate any deviation in the other eye *were* the muscle not contracted, which is an important fact and will be considered under *prognosis* and *treatment.*

The majority of blind eyes (although having no incentive to fix upon the observed object) do not wander or deviate from their normal position. Should such an eye have *one* abnormally powerful muscle, I do not think it strange or especially interesting if the eye should wander from its normal position in the direction of this muscle.

It cannot be denied that a muscle during a convulsion may become thoroughly contracted and remain so permanently. No other cause is found for the strabismus, and the history positively states that the eye became turned during a convulsion. If these cases exist they are very rare, and it is somewhat difficult to prove that there is not another element in the case which caused the squint. The accommodation having been reduced from sickness, it is urged that during the convulsion the child discovered for the first time the advantage derived from strongly converging one eye, and therefore continued to squint.

I think, however, that I have seen cases where simple contraction of the muscle during a convulsion caused the squint.

Another rather rare but interesting cause of squint is explained by the following case.

A young man was brought to me to be operated on for strabismus, who showed this interesting peculiarity. He was highly astigmatic and hyperopic. The vertical curve of his cornea was normal, while the horizontal curve was too flat. His father said he could not make out a five-dollar bill without rolling the right eye strongly toward the nose; then, holding the bill straight in front of him, he would be uncertain of its denomination till he carried it far to one side. He overcame the difficulties of having a short eye by strong convergence. He increased the refracting power of the horizontal meridian of his left eye, by looking obliquely through the lens. How this is brought about will be seen by looking obliquely through a magnifying-glass. The tendency of the eyes to deviate vanished as soon as a glass was given with which he could see without going through this manœuvre. Several, without any idea as to the cause of this peculiarity, were anxious to operate on it.

Myopia (short-sightedness) is supposed generally to be connected with strabismus divergens. But it not unfrequently happens that the highest degrees of strabismus convergens are found in myopic persons.

I have observed this condition five times in my private practice during the past year. While, on the other hand, during a somewhat extensive clinical experience, I never was fortunate enough to see a case of the kind. Horner, of Zürich, told of a case he had observed, which had been treated at Guy's Hospital, London, for six months with iodide of potassium, as a case of paralytic squint.

This explains why there is so much variance of opinion as to the frequency of this form of squint.

As there is no satisfactory literature upon myopic squint, you will excuse me for omitting what I consider to be unsatisfactory reasoning, and detailing a few interesting cases. We will exclude all cases where convulsions could have been the starting-point of cortical cataract, and at the same time produced a contraction of the internal rectus, and also all cases where inflammatory action could have affected the muscles. We will simply try to demonstrate that there are high degrees of convergent strabismus existing in myopic persons, who never would have had it had they not been myopic.

Graefe described a form of strabismus convergens caused by the far point of distinct vision being so near that the constant efforts to produce the *necessary convergence* led to an abnormal development of the internal recti muscles. At all distances between six and twelve inches both eyes were directed at the object. As the object was removed beyond this distance there was double vision, and one eye then deviated inward. Mauthner says he never has observed a case of the kind, but has seen strabismus convergens where one eye was normal and only the deviating eye was *near-sighted*, but he also adds it was amblyopic, therefore the connection between strabismus and myopia is not clear to him. I have never seen a case like his, and I doubt very much, from his description of the case, if there were any connection between the myopia and the squint. If there was a connection in his case between the myopia and the squint, I am sure there is no man in the world to whom this connection is clear.

He says the eye is myopic and *amblyopic.* I am therefore inclined to believe that the eye wanders in the direction of an unusually powerful muscle as a result of its amblyopia, or has been drawn over by inflammatory shortening of the muscle. Some will say it deviated as the result of "*mechanical*" causes, the gradual lengthening of the globe resulting from the myopia.

The following family history is, however, sufficient to make one look upon the theory of mechanical causes resulting from a lengthening of the globe with mistrust:

The father is far-sighted, and has been operated upon in both eyes for strabismus convergens. The mother has myopia $\frac{1}{3}$; does not squint, and has hardly a normal amount of mobility in the direction of the internal rectii.

The first child is eighteen months old, has about the same amount of myopia, and has strong convergent squint. The internal muscles of both eyes are shortened, and their inward mobility is greatly increased. He can direct both eyes at a given near point. If this point is removed, he fixes upon it with either eye. The convergence, as a matter of course, increases in the deviating eye in the same proportion as it decreases in the fixing eye. When the observed object is brought nearer than a certain point, the eye with the greatest convergence appears to be the fixing eye, which never is the case in any other form of strabismus. This case corresponds well with Graefe's description. He says, however, that beyond a certain point objects were seen double. Owing to this child's age, I acknowledge my inability to say whether he sees double or not. Judging from the statement of an adult who was in exactly the above "fix" and did not see double, I doubt his seeing double.

The second child is nine months of age; very myopic in the right eye; less so in the left. Right eye converges decidedly; left eye only slightly. There is a point where both eyes fix. Beyond this point she fixes with the left, and nearer than this point she fixes with right eye. As she is only nine months old, she cannot answer questions regarding double vision, and I cannot answer them for her.

These questions very naturally follow: If the mother is as near-sighted as the children, why don't she squint? What is discoverable in the children that is not found in the mother? The mother was myopic from earliest childhood. The mobility of her eyes inward is rather less than it should be. Her internal recti have never been sufficiently strong to *tempt* her to try and converge for objects two inches distant. She has not learned to exclude one eye by turning the head and cutting it off with the nose; neither has she learned to close one eye when she observes near objects. We must therefore conclude that she converges both eyes at the nearest convenient distance, and contents herself with seeing objects through circles of diffusion or indistinctly. The point at which she observes an object is farther away than her far point of distinct vision. The children have extensive mobility of both eyes inward. They are provided with muscles which are sufficiently powerful to enable them to converge for the point where they see most distinctly. By bringing these muscles into constant use they have become hypertrophied, and they can no longer relax them sufficiently when the eyes are at rest to allow the optical axes to become parallel.

There is no unusual lengthening of the globes of the children's eyes as compared with the mothers. I think this factor has been given a much more important place, than it deserves, in the production of strabismus in myopic subjects. *A squint due* to paralysis of one of the recti muscles presents (so long as the paralysis is present) a very different picture from any form of squint caused by contraction, hypertrophy, or shortening of one of the recti muscles. The patient either sees double or gives a history of having seen double for a long time.

In convergent strabismus due to the shortening or contracting of a muscle, you do not get any history of double vision. If one eye "fixes" upon a distant object, the other eye has a given convergence. If the observing eye be covered, the converging eye will assume a normal position, will fix upon the object, and the covered eye will make a corresponding convergence.

This is not the case in paralytic squint. When the fixing eye is covered, the squinting eye does not assume its normal position, and the fixing eye does not make a corresponding convergence.

In cases of paralytic squint the same conditions may finally exist which are found in simple squint. The paralyzed muscle may nearly recover from its paralysis, so that there is only a slight preponderance of the internal over the external muscle. When these conditions are developed, this form of squint may be operated with the same advantage as simple squint. But if one operates while paralysis is present, he will only do harm.

There still remains a possible form of squint. If the visual spot should, during development of the eye, become situate unusually near the nasal side or on the nasal side of the optic nerve, it is plain to see that the eye must converge before it can fix upon a distant object. Graefe reports a case of the kind *Archiv für Ophthalmologie*, Band I., Abth. I., p. 435).

I never have seen a case of the kind, and never have seen any one who had. However, should convergent squint depend upon incongruence of the retinas, it is easily diagnosed. Cover the eye which is apparently the fixing one. If paralysis is not present and the other eye does not assume a normal position when observing a distant object, asymmetry of development or incongruence of the retinas must be present. That being present, operation is out of the question, as double vision would immediately follow if any change in the relative position of the eyes were attained.

Having considered the causes of squint from a purely mechanical stand-point, we will next consider it from a purely clinical point under the head of *Results, Prognosis, and Treatment.*

247 EAST FIFTIETH STREET.

Corrections of errors in RECORD, No. 21, vol. xvii. —Conditions removed which prevent (not present) squint. Anterio-posterior (not anterior posterior) diameter.

* * *

A SPRAY OF PERCHLORIDE OF IRON IN EPISTAXIS is recommended as often avoiding the necessity of plugging the nares.

ANTE-COLUMBIAN EXISTENCE OF SYPHILIS. — Dr. Gustav Brühl, of Cincinnati, has lately presented some new evidence of the ante-Columbian existence of syphilis in America. It consists in the discovery among old Mexican manuscripts of certain epithets which were applied to the Mexican deities. Thus one of them is called Tepeu, or syphilitic. Another god was called El Buboso, or the syphilitic. Dr. Brühl thinks also that he has discovered evidence of syphilis in prehistoric bones.

Reports of Hospitals.

CHAMBERS STREET HOSPITAL, N. Y.

Reports of Practice and Peculiarities of Treatment.

Service of Dr. W. T. BULL.

Reported by Geo. E. Moore, M.D., House-Surgeon.

DISLOCATION BACKWARD OF LEFT CARPUS.

A heavy weight fell on P. M——'s wrist, which was on the ground. The deformity was marked, and just the reverse of the "silver fork" of Colles, there being a marked swelling over the anterior lower surface of the forearm at the situation of the lower end of the radius. The hand was much displaced to the ulnar side, the depression being on the posterior surface of the forearm. All voluntary movements at wrist were abrogated. Manipulation showed that the the lower articular end of the radius was firm on the shaft; all its prominences could be mapped out. The lower end of the ulna could not be felt, owing to displacement of the hand. No crepitus on local mobility; on the contrary, the joint was stiff. After reduction of the dislocation, the landmarks about the wrist were all in a normal relation to each other and all perfectly firm.

Under ether the hand was carried well backward and then brought rapidly forward, while firm traction was made. This reduced the dislocation, and there was no tendency to reproduction.

Recovery rapid; in twenty days a slight stiffness at the wrist was the only remains of the accident.

SKIN-GRAFTING.

T. B——, æt. 32, applied for treatment February 13, 1879, suffering from erysipelas of the leg and foot thirteen days old. The disease rapidly advanced, and by the middle of March the destructive changes denuded the leg of its superficial structures from the malleoli below on each side to the patella above, the entire circumference of the leg being deprived of covering. From the lateral aspect of this raw surface a long strip of granulations ran up to the greater trochanter of the femur, the site of a sinus which had been split up. At this time the patient's general condition was very bad, and it was not until about the first of April that the granulating surface was in good enough condition to promise success from grafting. From this time skin-grafting was regularly performed up to the middle of September, and on October 1st the skin had completely covered the leg and thigh, 1,200 and odd grafts being used. The largest number planted at any one time being 228, and the smallest 5.

The grafting was commenced from above downward along the anterior surface of the tibia. On May 16th there was a strip of new skin one inch wide which united the skin at the patella with that over the ankle. Grafts were planted on each side so as to surround the leg. June 17th the strip was six inches wide. July 13th all of the outer, anterior and inner surfaces of the leg were covered with new skin, excepting two circular openings one inch in diameter on the inner surface. This left a narrow strip on the posterior surface of leg one and a half inch broad and ten inches long, all that remained of the former large granulating surface. October 1st found the entire surface covered with new skin—six months after the grafting was first commenced. On November 15th the patient was discharged cured.

The grafts were taken by picking up the superficial skin, down to and including the papillary layer, so as just to show dottings of blood on the point of a half-curved needle, and snipping it off with sharp scissors. Size of graft about as large as the head of a two-inch pin. The raw surface of the graft was laid on the granulating surface and covered with rubber tissue dipped in solution of thymol, of which the dressing consisted.

A number of the grafts were taken from patients in the hospital, some being from a colored man, and it was found that these at first lost color, then grew darker again, but finally lost all pigment. Grafts were taken from amputated arms and legs as long as four hours after operation, and invariably took well. Two hundred and twenty-eight were taken from a leg amputated for compound fracture, and of these only five did not take.

The grafts had a wonderfully stimulating effect upon the edges, which, when sluggish, would, under their influence, spring up to a new life.

The grafts apparently grew from a proliferation of their own cells, as seen in the black grafts mentioned above in which the black patches actually grew longer. The grafts near the edges grew most rapidly; each graft has a maximum of growth, usually about the size of a five-cent silver piece, then the edges grew sluggish and ceased to advance. The new skin has very little tendency to contraction as usually seen in cicatrices.

FRACTURE OF POSTERIOR LIP OF THE ARTICULAR SURFACE OF THE RADIUS, WITHOUT FRACTURE OF STYLOID PROCESS—"BARTON'S FRACTURE."

That such a fracture is ever seen is doubted by so many, the particulars of the following case may prove of interest.

I. M——, falling, struck on the palm of the hand which was over-extended, twenty minutes before examination. At the latter time there was but slight swelling about joint. No deformity and no ecchymosis. Voluntary movements at wrist painful, especially over extension point. On manipulation by grasping posterior lip of the articular extremity of the radius, and making a lateral sawing motion, a distinct mobility of a fragment of bone could be felt. This was made the more apparent by a softened condition of the tissues, due to the contusion. The mobility was appreciable on an up-and-down motion, as well as on a lateral one. The crepitus was long and marked. There was at the point of fracture a considerable local tenderness. The styloid process of the radius was normally firm, and could be moved only with shaft of bone. Patient did not return for treatment.

FRACTURE OF THE PATELLA AND OS CALCIS FROM INDIRECT VIOLENCE.

While W. R—— was carrying a heavy load downstairs he felt his knee give way. Two years before he had had the same patella fractured. It united well and caused no lameness. On examination a transverse portion of the right patella was found, the upper and larger fragment being drawn up two inches. There was also fracture of the os calcis of same side, the tuberosity being chipped off and drawn up by the muscles of the calf.

Treatment.—Adhesive straps held fragments of both fractured bones in position. Plaster-of-Paris splint applied at once from toes to upper part of thigh, limb, and foot being elevated in an extended position. Second splint three weeks later.

Result.—A ligament one inch long united fragments of patella. Firm union in the os calcis, with considerable thickening about the point of fracture. Motions in ankle and knee perfect. Discharged thirty-seven days after the accident, and ordered to wear posterior splint of leather, while walking, for one month.

DISLOCATION OF BOTH HUMERI.

A. W—— was seized from behind by two thieves, his forearms being flexed, his arms being drawn upward, outward, and backward. On examination a sub-coracoid dislocation of each humerus was found. An interesting point in the examination was, that, on each side, both before and after giving ether, Dugas's dislocation-test proved unreliable; for, the hand of the dislocated arm being on the opposite shoulder, the elbow could easily be made to touch chest-walls. The patient, it may be stated, was neither stout nor thin. Both bones had been dislocated before this accident, but never at the same time. Reduction was easily accomplished under ether by drawing the arm away from body to a right angle, and then making direct pressure on the head of the bone toward the glenoid cavity.

Progress of Medical Science.

Operative Treatment of Pyo-nephrosis Calculosa.—Dr. Petersen (*Berlin. klin. Woch.*, April 5, 1880) reports a case of this kind, which terminated favorably, the patient being restored to health. A woman, thirty-nine years old, had suffered pains in the right hypochondriac region for about eight years. Her appetite and digestion had remained satisfactory; her menstruation and other functions were not disturbed. In the fall of 1877 the pains became more severe, sometimes intense colics came on, and abdominal enlargement was also noticed. The urine was generally turbid, and showed a deposit; sometimes, however, it appeared normal. Febrile action was now developed, her appetite was lost, a harassing cough supervened, and the patient became rapidly emaciated. Examination revealed fluctuation in right side, and a large tumor could be distinctly palpated. The symptoms, together with the results of examination, pointed to the right kidney as the probable seat of the affection. An exploratory puncture with a hypodermic syringe, armed with a long canula, was made, and a thick yellowish fluid was found. The microscope revealed epithelial cells in a condition of fatty degeneration, crystals of uric acid, red globules, and numerous pus-corpuscles. About a quart of this matter was then withdrawn by means of the aspirator. The canula on being pushed inward came in contact with a hard body, and the presence of renal concretions was thus made apparent. Owing to the unpromising surroundings of the patient, and the inability to remove her to a hospital, a radical operation was deemed inadmissible. It was determined, therefore, to create a fistula and then practise gradual dilatation of the same. The aspirating canula was allowed to remain in situ, and laminaria tents of gradually increasing calibre were successively introduced Antiseptic precautions were employed during all these procedures. After some time the finger was introduced through the opening, but the concretions could not be removed by this means. With the aid of a strong dressing-forceps, fragments of the calculus were readily removed. This operation was repeated, and after the renal pelvis was found to be cleared of all remaining débris, drainage-tubes were inserted, and the wound irrigated with carbolic acid solution. The subsequent course of events was quite satisfactory, the purulent discharge at first very profuse, gradually grew less, the wound slowly closed, the drainage-tubes were removed six weeks after the operation, and the fistula was at length allowed to heal. The urine, however, still remained turbid, and several weeks later some pain was again experienced. This induced the patient to thrust a knitting-needle into the newly formed cicatrix, and some pus was said to have escaped. The patient, apprehensive of a return of the pains, insisted on keeping the fistula artificially opened. Eighteen months have elapsed and she continues in good health, discharging all her domestic duties without the slightest discomfort.

Diabetes Insipidus Treated with Ergot.—In the *British Med. Journ.*, Dec. 25, 1875, is recorded the case of a man who suffered from diabetes insipidus, and was successfully treated with ergot, after the failure of jaborandi and other remedies. Half a drachm of the liquid extract of ergot, every three hours, reduced the urine in twenty-four days from twenty pints to a pint and a half; increased its specific gravity from 1,002 to 1,017; and removed the excessive thirst and other distressing symptoms from which he had suffered for two years. A few days ago the reporter of the case, Dr. Murrell, accidentally met the patient and was told that he had never had a day's illness since he left the hospital, four and a half years ago. His urine was normal in quantity and he did not suffer from thirst. He was strong and well in every way, and able to do a good day's work. The ergot cured him completely, and Dr. Murrell adds that it is to be regretted that this mode of treatment is not more commonly employed in these cases. —*The Brit. Med. Jour.*, May 8, 1880.

Follicular Adenoma of the Conjunctiva.—M. Gosselin (*Gaz. des hôp.*, April 29, 1880) describes what is called by him a new variety of conjunctival tumor, of benign character: A youth, 16 years old, was subject to repeated attacks of the common affection known as hordeolum. These would sometimes end in slight suppuration, or would pass off by resolution. The formation of the tumor in question was attributed by the patient to the prolongation of one of these hordeola, which, failing to undergo suppuration, became chronic, as it were. For about a year there existed an uncomfortable swelling on the free border of the right lower eyelid. Redness and induration also became manifest, but the tumor never bled, and at no time presented ulcerations. It was painful on pressure. It kept up a continual congestion of the inferior lid, but never gave rise to bulbar conjunctivitis or corneal affections. Notwithstanding its small size, it became the occasion of considerable discomfort. It did not present the appearance of a conjunctival polypus, nor did it at all resemble epithelioma. Sarcoma or fibrous tumor was thought of, but the histological examination proved otherwise. It was found to consist of the hypertrophied follicles of the Meibomian glands, presenting glandular vesicles with heaps of epithelial cells. The etiology of this follicular adenoma of the conjunctiva appeared from its minute structure. The repeated inflammatory attacks led to an abnormal development of the pre-existing gland follicles, and quite probably also to their new formation. Treatment by compression and astringent collyria was deemed too tedious. Accordingly the projecting mass was snipped off with curved scissors and the desired effect obtained.

STUDYING PHTHISIS.

These are troublous times to the student who wishes to gain clear pathological ideas on the subject of phthisis. As regards this particular question, the educational vicissitudes of the physician who began his studies, say, a decade ago, have been something like the following: He was probably first brought to believe the views of Virchow and Niemeyer, that chronic phthisis is a scrofulous inflammation of the lung, with which tubercles might or might not be associated. He distinguished catarrhal and fibroid types, according as cheesy pneumonia or connective tissue proliferation predominated. There was no such thing as chronic tuberculosis properly so called; and acute tuberculosis was rarely a synonym for acute phthisis, except among children. Tubercle was put quite in the background.

Being well grounded in these views, he could scarcely escape some confusion upon learning, from Ruehle, that, clinically and pathologically, chronic phthisis has three different types, these being the fibroid, the broncho-pneumonic and the bronchitic. The scrofulous diathesis is at the bottom of the second and third, and perhaps also of the first; but the tubercle is still ignored as a primary factor. Having mastered the distinctions of Ruehle, he turned perhaps to Rindfleisch. Here he learned that phthisis begins generally with a bronchitis. This, acting upon a scrofulous system, excites a crop of tubercles at the entrance to the air-vesicles, and these form a tubercular infiltration which is the anatomical basis of the disease. The future progress is, in part, that of a cheesy pneumonia, but the whole process is essentially a tuberculous one, and that name should be used.

As if to still further demoralize the investigator, a place in Reynolds's system of medicine is given to the views of Dr. Bennett. This acute pathologist believes in tubercle with all his heart, but not in German tubercle. It is not a cellular neoplasm, but a coagulation of the molecular blastema transuded from the blood. This causes all the anatomical appearances found in the phthisical lungs. There is, according to him, no such thing as cheesy pneumonia.

Very recently Professor Cohnheim has announced that tubercular phthisis, as well as what has been known as catarrhal phthisis, is the result of a specific infection, the tubercular virus; that phthisis is closely analogous to syphilis in its pathological history. We have reached again the apotheosis of tubercle, and the anxious learner is more than ever in despair. A little more darkness is turned upon the subject in a recent lecture by Dr. Wm. Pepper. He gives us an additional form of phthisis, the croupous. This with the tubercular, catarrhal, and fibroid, makes four in all. It is a classification that is entirely unwarranted and can only add to the student's perplexity.

We advise the student to stick to his Niemeyer and give cod-liver oil, while waiting for the better settlement of the pathology and classification of phthisis.

THE PHYSICAL INJURY TO SHOP-GIRLS.

The subject of the injury done to shop-girls by their long hours of compulsory standing has been agitated with some good results in Dublin, London, and other English cities. It is an old question, and has been often and fruitlessly discussed in New York. There is no reason why it should be allowed to rest, however, until some result is accomplished here, and we therefore bring up the matter now.

There are two ways in which some reform can be brought about as regards this form of cruelty to women. One is by appealing to the humanity of the shopkeepers and of the ladies who shop; the other is by enacting a law limiting the number of hours per day in which shop-girls shall be compelled to stand upon their feet.

We have but little faith in the appeals to humanity. They have been often enough made; but "business is business" with the heads of the houses, and individuals must adapt themselves to the inexorable laws of profit and loss. As for the ladies, they must know and see every new thing.

It is possible, however, for the State to come to the rescue and to regulate the matter by law. And in this way alone is there likely to be any relief obtained. From various communications made to the press in this country and England by the shop-girls themselves we gather that they do not hope for redress except in this way. In order that any legal measure may be enacted, however, it will be necessary to have positive statistical evidence from physicians. We cannot put the matter better than by quoting part of a joint letter from several shop-girls to the *New York Herald* of recent date:

"In answer to the 'Shop-Girls' Wrongs,' I would state that an effort tending to ameliorate their condition was made some time ago, and has not been given up, although hindered very much by the young ladies themselves, as they are unwilling to give any information for fear of losing their positions. After considering the subject, we are convinced that the only way to reach the root of the matter is by law. Proprietors who are blind and deaf to the sufferings of their own employees cannot be reached by sympathy, but by law.

"In order to arrange the matter in a legal form, it must be proved that the standing of saleswomen for nine and a half hours is an injury to the commonwealth. Statistics proving the sad effects that have arisen from continued standing in a small space in our own stores is the basis upon which the whole agitation of the question depends. It is with the view of obtaining such information from physicians and saleswomen for use in preparing and advocating the passage of a law remedying these evils that I write this letter."

There are probably hundreds of physicians in this city who could give positive evidence upon the above points. We should be glad to have the subject discussed and to receive all the facts that might be contributed.

This is eminently a matter for the medical profession to take up; and if the evils are anything like what it is currently believed they are, it is due that the profession lend its help to see that they are righted.

THE ASSOCIATION FOR THE PROTECTION OF THE INSANE.

At the Annual Conference of Charities and Correction, held in Cleveland a short time ago, an entire day was given up to discussing the subject of the care of the insane. The regular committee made its report upon the question, and half a dozen other papers were read, two of them being by asylum superintendents. The general tenor of the papers and discussions was toward a reform in many of the methods now used in caring for the insane. The various evils which have been pointed out from time to time in this and other journals were acknowledged and condemned. Suggestions of the line in which improvements should be made were embodied in a series of resolutions, unanimously adopted, of which we shall present an abstract hereafter.

Finally, a national association for the protection of the insane was organized. Such an association has been contemplated ever since last fall. It has at last begun an actual existence, and under promising circumstances. It is endorsed by those who have a scientific knowledge of the matter in hand, as well as by those whose intelligent and generous philanthropy has already done so much for the unfortunates. The society will make the question of the care of the insane a national one, and will form a centre for united and persistent action in the cause of reform. We could wish that the name of the association was not so aggressively suggestive. It is understood that the special object is to secure reform in the care and treatment of the insane, not to be the palladium of this class against rapacious superintendents. The two points are not absolutely identical; and it is not necessary to antagonize the superintendents by a pretentious nomenclature.

The prominence given to the subject of insanity at the recent conference indicates how widely the belief in its importance has extended. The conclusions arrived at and the organization effected show that the merits of the question are beginning to be properly appreciated, and give promise of a certain improvement in the future.

PAPERS VERSUS DISCUSSIONS.

There has been a great deal of debate at various times as to which is the more valuable, the papers read before medical societies or the discussions which they excite. The one, it has been said, gives us the results of closer study, the other of wider experience. In the former, opinions are more likely to be warped; in the latter they may be loosely and carelessly given.

A contribution to the settlement of this question was recently furnished at the session of a State medical society, not a thousand miles from a Hoosier centre. The contribution, which comes in the form of a historical incident, occurred as follows: The president opened the meetings with a well-considered speech, in which he forcibly depicted the superior value of discussions over papers. We will not say whether it was a *post hoc* or a *propter hoc*, but at precisely thirty minutes past ten that morning, Dr. A and Dr. B entered into a discussion, dispensing entirely with the hackneyed conventionality of a preliminary paper. The discussion speedily passed from purely scientific to practical, and at last to entirely personal matters; and it became conducted with that warmth of language and freedom from parliamentary and grammatical restraints which occasionally animate the interchange of thought upon the rich prairies of the glorious West. The fact is, or it is related, that Dr. A and Dr. B used very violent language, and finally Dr. A knocked off Dr. B's hat and then kicked him down-stairs. On motion, the matter was referred to the Committee on Ethics.

Upon similar occasions, in other cities, we have known the matter to be referred to the justice, and the actors to the station-house. But this new plan seems a better one, as it is pleasanter for the doctors and enlarges the scope of our various Codes of Ethics.

In this case the committee promptly reported that Dr. A deserved a public reprimand from the president, as having increased the interest, perhaps, but lessened the value of discussion. At the appointed time Dr. A stepped jauntily up to the platform and said that he was ready. He was informed by the President that he was a bad man; not very bad, perhaps, but bad enough. The doctor received the announcement with cheerfulness and self-possession. At its conclusion he thanked the President for letting him off so easily, thanked the society for the interest it had taken in his recent polemical efforts, and in his subsequent ethical condition, and finally thanked the mayor of the city for fining him so large a sum as $31.20, showing as it did that he was no ordinary man, and disturbed the peace in no ordinary way.

Thus ended that particular discussion. As for the light it throws on the question at issue, it tends to fix us in the belief that discussions are, as a rule, non-expert affairs, and are liable to have more of a dramatic and personal than of scientific or practical value. And if discussions must constitute a prominent feature of State Societies, we recommend a closer study and a more rigid application of Cushing's Manual and the Code of Medical Ethics.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 26, 1880.

Dr. T. E. Satterthwaite, President, in the Chair.

REPORT OF MICROSCOPICAL COMMITTEE.

Dr. Peabody presented a specimen for a candidate for admission to the Society.

EXCISION OF ASTRAGALUS.

Dr. Mason presented an astragalus which he had removed from a man aged 57 years, who had sustained in January last a compound fracture of the tibia and fibula just above the ankle, and a dislocation outward of the astragalus. The patient came under the observation of Dr. Mason at the Roosevelt Hospital on the 20th of March last. The fractures had united, but the astragalus still remained dislocated outward. Over the prominent portion of this bone was a granulating surface two and a half inches in circumference, through which bare bone could be detected. The astragalus was completely turned upon itself. The foot was entirely useless to the man, he being unable to bear any weight upon it, and it was in the position of equino-varus, the sole looking inward. The operation for the removal of the bone was performed on the 27th of March. The limb was placed in a plaster-of-Paris splint and a drainage-tube inserted. Complaining of pain at the end of the third day, the limb was slung. At the end of three weeks the patient was able to walk on his crutches, and for a week before the time of the presentation of his case the patient was able to get about with a cane. After the wound was healed there was a tendency to eversion of the foot. This was counteracted by rubber bands suitably applied to loops of adhesive plaster.

RUPTURE OF AN OLD CICATRIX OF THE COLON—SUDDEN DEATH.

Dr. Heinemann presented a small piece of the descending colon of a patient who died from shock, within eight hours, from the rupture of an old cicatrix. The patient, a spinster, aged 40 years, was taken ill on the evening of May 14th with an ordinary attack of diarrhœa. The discharges continued from Friday until the Tuesday evening following, when they ceased. On Saturday evening she became restless, and on Sunday the 23d there was a temperature of 102° F., and a pulse of 100. On Sunday evening the temperature fell to 100° F. On Sunday night she became a little more restless, but no other symptoms presented themselves. On the morning of the 24th Dr. H. saw the patient. The pulse was then 140, and she was somewhat delirious. At noon the countenance had changed completely; the features were pinched, the pulse was 160, and the respiration 53. At 4 P.M. the patient was somewhat more delirious, but still rational, and within one hour afterward she lost consciousness. She continued to sink, and died at half-past eight.

On Monday morning the symptoms looked like those belonging to masked typhoid, in which the rupture of an intestinal ulceration had occurred.

At the autopsy, Peyer's patches were found to be slightly swollen, the solitary follicles a little enlarged, but there was no enlargement of the mesenteric glands.

In the descending colon there were cicatrices of old ulcerations. In many places the mucous and muscular coats were destroyed, leaving only the peritoneal. In the middle third of the descending colon there was a patch the size of a three-cent silver piece, and another the size of a ten-cent silver piece, both of which had ruptured into the peritoneal cavity. The peritoneal cavity itself was empty.

The interest in the case centered in the fact that the patient died from a rupture of an old cicatrix, and that the accident was entirely unconnected with the last illness. The patient had during her lifetime suffered many times from attacks of diarrhœa; in fact, she had, according to her own statement, learned to look upon her bowels as her weak part. Dr. A. Clark, who had seen the case in consultation, and who had diagnosticated the condition, informed Dr. H. that he (Dr. C.) had seen a similar case last November, in which also the symptoms of collapse came on quite suddenly. In that instance, also, a diagnosis of rupture of intestine was made before death.

FIBRO-CYSTIC TUMOR OF VELUM PENDULUM PALATI.

Dr. Alfred C. Post presented a tumor removed from the soft palate, with the following history:

Margaret Cadwell, æt. 45; admitted into Presbyterian Hospital May 20, 1880, with a tumor occupying the right half of the velum palati. She had only noticed it about a month before her admission. It was not painful, and it did not give rise to any serious inconvenience. She attributed it to the irritation arising from false teeth. Before the operation I did not come to any definite conclusion as to the benign or malignant character of the morbid growth. I operated on the 22d of May, being prepared to make a free use of the Pacquelin cautery, if I had found the tumor firmly adherent to the velum in which it was imbedded. The patient being etherized, I pried the mouth widely open, and made a free incision through the buccal mucous membrane covering the inferior surface of the tumor. I ascertained at once that the tumor was loosely attached, and I succeeded, without difficulty, with the aid of a blunt tissue-separator, in enucleating it. The tumor was of a firm texture, apparently composed of fibrous tissue, with a small cyst of the size of a pea at one extremity. The length of the tumor was about four centimetres, and its breadth about three centimetres. I believe that tumors originating in the velum are of rare occurrence.

Dr. Post also exhibited a specimen of

ENORMOUS ENLARGEMENT OF THE UPPER END OF THE TIBIA,

with the following history:

Frederick Lenckel, æt. 25. Admitted into the Presbyterian Hospital Nov. 13, 1879. He had had disease of the upper end of the tibia for eight or nine years. On the 15th of November I removed a large amount of soft bony tissue infiltrated with pus, and soon after that date reported the case to the Society.

Since that time, the large cavity which was left in the bone has diminished in size, being partly filled with healthy granulations. But the patient has, for many months, been confined to his bed, his knee is flexed at an angle of about 140°, and his general health is delicate. He has a protracted cough, with a certain amount of dulness on percussion beneath the clavicle, and the expiratory murmur is prolonged. Under these circumstances I called a consultation of the surgeons of the hospital, and it was decided that the limb should be amputated. I performed the operation May 25th. I amputated at the knee-joint, making an oval incision, descending much lower at the posterior part of the limb than at the anterior. I was induced to operate in this manner by the fact that there was no healthy integument in front, extending much below the upper extremity of the tibia. Having dissected up the integument, I opened the joint, divided the crucial and lateral ligaments, and severed the leg from the thigh. There was some difficulty in accomplishing this part of the operation, owing to the very limited mobility of the knee, and to abnormal osseous deposits in the fibrous tissues. An unusual number of vessels required to be tied. The wound was then thoroughly washed with a carbolic lotion, 1 to 20. A long drainage-tube was then inserted across the limb, behind the condyles of the femur, having several large eyes within the limits of the wound, and the edges of the integument were accurately adjusted by numerous fine sutures. Three layers of carbolized gauze were then applied over the stump, perforated to allow the transit of the two ends of the drainage-tube, and a gauze roller was applied over the whole, allowing both ends of the drainage-tube to project two or three inches beyond the dressings. Carbolic lotion, 1 to 40, was then injected with a syringe through the tube, until it came out clear. This injection was directed to be repeated three times a day. The dressing of the stump was in accordance with the admirable method suggested by Prof. T. M. Markoe, and described by him as "through drainage."

EPITHELIOMA OF CHEEK—EXTIRPATION—VERY EXTENSIVE PLASTIC OPERATION.

Dr. Post also presented a specimen of epithelioma of the cheek, with drawings and diagrams, and with the following history:

Michael Kerns, æt. 61. Admitted into the Presbyterian Hospital May 13, 1880. He had an extensive epithelioma of the left cheek, extending from the ala nasi to the border of the masseter muscle, and from the lower lid down to a horizontal line midway between the nostril and the angle of the mouth. The patient first noticed a tumor on the cheek three years ago. The surface has been ulcerated during the last nine months. I removed the diseased mass on the 15th of May. The patient having had a hypodermic injection of morphia, and being etherized, I removed a square flap of integument about six centimetres in diameter, including the disease, and extended the vertical incisions down to the base of the jaw, thus forming a large flap to cover the denuded parts. I then dissected up the flap from the subjacent parts, and curved the incisions below and behind the base of the jaw, toward the lobe of the ear, so as to take off the tension from the flap, and to allow it to be drawn up to the level of the lower lid. In the course of the operation several arterial branches of considerable size were divided, and were secured with ligatures. After securing the vessels and thoroughly washing the wound with a carbolic lotion, 1 to 40, I introduced a drainage-tube from the upper to the lower part of the wound, and then brought the edges of the wound together with fine sutures. The edges of the wound, including the borders of the peduncle, were brought together at every point, except where they were separated by the drainage-tube. Before I applied the sutures I jerked off the ligatures from the arteries which had been tied, and apparently without any immediate injurious result. But I would not recommend this practice to be followed, for secondary hemorrhage occurred after the lapse of a few hours, and it became necessary to remove a large number of the sutures and to reapply ligatures to three of the wounded arteries. The lips of the wound were again secured with sutures, but not with as much ease as at first. The drainage-tube was removed at the end of three days. Some separation took place at the junction of the flap with lower lid, and at the lower part of the peduncle. But the greater part of the wound united by the first intention, and there is reason to believe that the face will be very little disfigured by the operation. Some inconvenience will be likely to occur from the growth of hair from the flap in the vicinity of the eyelid, but the occasional plucking of the hairs, one by one, will remedy this evil.

In conclusion, Dr. Post stated that Dr. Shrady had, a year or more before, performed a similar operation upon the cheek of a man with epithelioma. In Dr. Shrady's case, however, the growth was upon the prominence of the malar bone.

Dr. G. F. Shrady remarked that in his case the entire thickness of the cheek was excised, with the morbid growth, by means of a quadrilateral incision. This deficiency, which measured two and a quarter inches in one direction and one and a half inches in another (vide Medical Record, vol. xv., p. 82), was supplied by continuing the vertical incision directly downward to a sufficient depth, and then curving the peduncle rather abruptly backward until it terminated on the posterior aspect of the neck, and behind the mastoid process. The flap was brought up with the greatest ease; there was no tension at any point, and there was union by first intention throughout the entire extent of the wound, and no deformity.

Dr. Tansky presented a specimen of pelvic cellulitis and peritonitis, the result of over-distention of the rectum in a puerperal woman.

Dr. Hailes, of Albany, by invitation of the Society, exhibited and explained his microtome. By this apparatus it was shown to be possible to make the most perfect microscopic sections of any appreciable thinness with the greatest ease and rapidity. (See p. 109, Art. "An Improved Microtome.")

Dr Peabody remarked that the sections which he had seen were very perfect, being of extreme thinness, and of exact conformity throughout.

Commendatory remarks of the method and its results were also made by Drs. Satterthwaite and Carpenter, when, on motion of Dr. Briddon, a vote of thanks was tendered to Dr. Hailes for the presentation of his beautiful and useful apparatus.

ANEURISM OF ARCH OF AORTA.

Dr. Delavan exhibited two specimens of aneurism of the aorta, with the following histories:

F. B., age 32; English; married; coachman. Patient presented himself for treatment at the clinic for diseases of the throat, at the Demilt Dispensary, July 20, 1879, and gave the following history:

Family history good. Habits temperate. Denied venereal. Had never suffered from rheumatism. Had always enjoyed good health till five years ago, when he had an illness which lasted for six weeks, in the course of which he suffered with precordial pain, shortness of breath, palpitation of the heart, and inability to lie down. From these symptoms he never entirely recovered. During the past winter he suffered from short, hacking cough and night-sweats, but no expectoration, and progressively deteriorated as to his general condition. One week ago he was suddenly seized with incomplete aphonia, accompanied occasionally by a sensation of choking. At the same time he began to complain of precordial pain, cough, dyspnœa, great weakness, and anorexia. When first examined at the dispensary he complained of the above general symptoms; he appeared fairly nourished. His expression was anxious; his voice hoarse and rough at times, but generally reduced to a whisper. The laryngoscope revealed a condition of hyperæmia throughout the larynx and vocal cords. There was complete paralysis of the left vocal cord, while the movements of the right cord appeared to be limited. Examination of the chest revealed dulness, with increased vocal fremitus at the apices of both lungs, together with prolonged harsh respiration and friction râles. Pain and tenderness in dorsal region. Heart impulse strong and full. Frémissement cataire very strongly marked. Loud bruit over sternum and transmitted all over precordium and upper part of the right side of chest. Diagnosis: stenosis and insufficiency of the aortic valves of the heart, large aneurismal dilation of ascending and transverse sections of arch of the aorta. Pressure upon left recurrent laryngeal nerve.

As the patient lived out of town, it became necessary for me to place him in the hands of a friend, to whom I am indebted for the subsequent history of the case.

During a period of five weeks his condition became rapidly worse, the most distressing symptom being dyspnœa, which frequently became paroxysmal, especially at night. He complained of pain and a tingling sensation extending down the right arm and hand. The left radial pulse was much stronger than the right, and the veins in the right arm much distended; there was also considerable dysphagia, almost complete insomnia, respiration loud and crowing, cough very troublesome, with expectoration of considerable amount of bloody sputa. Action of diaphragm spasmodic; was obliged to bend forward to breathe, veins all distended, marked bulging of upper part of sternum.

Sept. 12th.—Patient was suddenly seized with a severe attack of dyspnœa; pulse feeble and irregular; marked cyanosis. He rallied and became comparatively comfortable, but six hours afterward the dyspnœa returned and the patient died.

Autopsy, 18 hours after death.—Body well nourished; rigor mortis well marked; œdema of both legs; abdomen normal; diaphragm: right side, fourth rib, left side, fifth rib; thorax: there are a few adhesions at each apex, elsewhere none at all; no fluid in either side; the aorta is obviously much dilated at the summit of the arch, the thoracic viscera being removed entire, the following conditions are found: The heart is somewhat enlarged, chiefly at the expense of the left ventricle; the aorta is atheromatous throughout, there being but few small patches of sound tissue; it is nowhere calcareous, but is ulcerated in places; the aortic valves are stiffened, and the edges thickened; the other valves are normal; about two inches above the aortic valve the aorta becomes suddenly dilated, forming a sac, which is nearly spherical in shape, with a diameter of about 3½ inches. This sac presses upon the trachea so as to materially lessen its calibre. It involves the whole of the arch of the aorta, and about 3 inches of the descending aorta is dilated, forming a fusiform sac, whose diameter is about 1½ inch. The posterior wall of this latter sac is firmly adherent to the bodies of the sixth and seventh dorsal vertebræ. It has eroded both their bodies to the depth of about $\frac{1}{12}$ of an inch and over an area of 1 by 1½ inch.

Lungs congested and œdematous; old fibrous induration at both apices. Brain and membranes, spleen, stomach, and intestines, normal. Liver fatty. Kidneys intensely congested.

Microscopical examination of kidneys.—They are found to contain many hyaline casts. No miliary aneurisms found in vesicles of the brain.

F. F., age 35; single; United States; coachman; family history good; hard drinker; denied syphilis.

For fourteen years patient suffered from caries of the spine, which increased in severity during the past five years. Two years after commencement of the disease patient began to suffer from cough, night-sweats, anorexia, pain in the chest, and occasionally œdema of the feet.

One month before admission to the New York Hospital cough became more troublesome; there was also marked dyspnœa and occasional slight hæmoptysis. On admission to the hospital the patient was weak and somewhat emaciated. Examination revealed marked cyphosis, the most prominent point being the ninth dorsal vertebra. There was also rude respiration, and dulness at the apices of both lungs. The voice was husky, and at times reduced to a whisper. Deep inspiration was accompanied by a peculiar crowing noise. The radial arteries were atheromatous.

For four weeks following admission to the hospital the prominent symptoms were severe paroxysmal attacks of coughing, with, at times, expectoration of blood, dyspnœa, stridulous breathing, and pain in the dorsal region. A plaster-of-Paris jacket was at this time applied, with the result of affording some relief; six weeks following admission the attacks of dyspnœa began to grow alarming, cough very distressing, and voice husky and indistinct. Eight weeks after admission patient was suddenly seized with a violent spasm of the glottis, became deeply cyanosed, and suddenly died.

Autopsy.—Body well nourished. No œdema; marked cyphosis both in dorsal and in lower cervical regions, as well as double lateral curvature. Head, brain, and membranes normal; abdomen normal; diaphragm: right side at level of third rib; left side at level of fifth rib. Thorax: old adhesions everywhere on left side, none on right side. Heart: valves normal, muscular tissue good. A few patches of atheroma in aorta. Lungs: right lung normal, except some œdema, some reddish mucus in bronchi; left lung intensely congested and œdematous. Two old patches of fibrous thickening in upper lobe; near apex a small cavity about the size of a chestnut, containing cheesy pus; bronchi contain reddish mucus. Spleen normal. Kidneys intensely congested, hard and firm; markings good. Stomach: mucous membrane slightly thickened. Liver and intestines normal. Other organs: tongue, larynx, trachea, œsophagus, arch of aorta, descending aorta, removed *en masse.* Just before the origin of the left subclavian artery is reached, an opening is seen in the aorta which is irregularly circular in shape, with a diameter of about three-fourths of an inch. A firm red clot projects from this into the aorta. On removing this clot a sac is disclosed, which is about two inches in diameter and nearly spherical in shape. On opening larynx and trachea, this is found to communicate with the trachea just above the bifurcation by two small, irregularly shaped openings, through which a probe passes freely. Just above these are two small ulcerations in the mucous membrane of the trachea which do not reach the aneurism. There is some pinkish mucus in trachea, but no blood. The rings of trachea in contact with aneurism are calcareous.

Microscopic examination: Kidneys show numerous fatty tubes.

CARCINOMA OF THE STOMACH, LIVER, AND MEDIASTINAL GLANDS—ABSCESS BURSTING INTO ŒSOPHAGUS AND LUNG, CAUSING GANGRENE—DEATH FROM PULMONARY HEMORRHAGE.

Dr. Satterthwaite presented the following case as a curious instance of the way in which death may be caused in carcinoma of internal organs.

J. K——, æt. 43; German; laborer; entered the Presbyterian Hospital April 6, 1880. His previous history, so far as gathered, was unimportant, and had no bearing upon the disease which ushered in the fatal symptoms. The first marked derangement of his health was observed in September, 1879, when he had repeated attacks of vomiting, first expelling the contents of his stomach, and then clear mucus. These expulsive efforts gave him no pain. During the latter months of his life there was cough and muco-purulent expectorations, or something which was so regarded. Particular attention was not directed to this point, as the case exhibited many of the prominent symptoms of phthisis. During the early months of the year he had afternoon fever, followed by sweating, but the vomiting had stopped. His appetite was now good, although digestion was poor. Starchy and fatty foods were most acceptable, but albuminoids gave distress. Examination of the urine yielded nothing abnormal. In April last, just prior to death, he had hæmoptysis, as was supposed, but he was never confined in bed. One day, while in the surgical ward, he was overtaken by a sudden hemorrhage. He then fell upon the floor, the blood filling his mouth, throat, and nose. Cyanosis was complete. Though efforts were immediately made to rally him, they were unavailing.

At the post-mortem examination, the contents of the thoracic cavity, together with the tongue, pharynx, and larynx, were removed *en masse.* On opening the œsophagus from behind, it was seen to be ulcerated at two points, one on a level with the auricular ventricular openings, and therefore in the horizontal plane of the third costal cartilages, the other a half-inch above. Both openings were about three-quarters of an inch in diameter, and had ragged edges. They were manifestly caused by the breaking down of degenerate glands. Though in both cases the lumen of the œsophagus had been destroyed, in the case of the upper ulcer, the gland, or its remains, pressing into the opening, occluded the opening, so that no food could escape. The lower ulcer, however, had established a communication with the lung by a fistulous passage which passed forward, downward, and to the right. This track, which barely admitted an ordinary lead-pencil, passed immediately behind one of the two pulmonary veins which carried the blood into the auricle from the right lung. It also lay close to the main division of the bronchus, which leads to the right lower lobe. In this situation it had excavated for itself a large cavity the size of one's fist. At first glance it was thought that the case was simply one of ordinary fibrous phthisis in connection with carcinoma. On closer observation, however, it was seen that the cavity was gangrenous, and that there were in reality none of the fibrous septa that belong to fibrous phthisis. Nor were there any miliary tubercles or caseous collections or consolidations of any kind in this lung. The cavity was similar to those found in the lung when foreign substances, such as food or solid matters, have accidentally made their way into its texture. Owing to progressive gangrene, there had been ulcerations into a small pulmonary vessel, whence the hemorrhage, which mainly, if not wholly, passed into the œsophagus, and from thence downward into the stomach, and upward into the mouth and nose.

Surrounding the trachea and bronchi were numerous other enlarged and softened lymphatic glands. On removing the stomach it was plain that this organ was the seat of the primary disease. At the pyloric extremity, evenly involving the whole circumference, was a cirrhous infiltration, which gave the walls a thickness ranging from one-half to three-quarters of an inch. The orifice was so narrowed as to admit only the little finger, and that with difficulty. The stomach also was dilated, and its lower margin reached to the level of the umbilicus. The liver was filled with cancerous nodules, ranging in size from a pea to a large marble. The spleen was soft, but otherwise normal. The heart was small, flabby, and its valves atheromatous. The left lung was normal.

The most reasonable explanation of the case was that the disease first appeared in the stomach, as indeed the clinical history indicates; that later the liver and mediastinal glands were infected. A large gland becoming enlarged and softened, discharged both into the œsophagus and lung. First these readily gained access to the lung, causing gangrene, which in turn, encroaching upon the calibre of the pulmonary vessels, gave rise to the hæmoptysis, and indeed, secondarily, to hæmatemesis. Cases similar in many respects are on record, and von Ziemssen and Zucker record one in their chapter on diseases of the œsophagus, in Ziemssen's Cyclopædia.

The daily exacerbations of fever accord with this view, and the sputa might, in ordinary clinical language, be described as "muco-purulent."

◆

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Second Annual Convention, held May 31, 1880.

First Day—Morning Session.

The American Laryngological Association convened at Delmonico's, Parlor No. 10, in New York City, May 31, 1880, and was called to order at 11 A.M. by the Secretary, **Dr. George M. Lefferts**, of New York.

In the absence of the President and Vice-President, on motion of Dr. Knight, Dr. J. Solis Cohen, of Philadelphia, was elected Chairman.

The Secretary, **George M. Lefferts**, of New York, then read his Address of Welcome. He spoke in cheering terms of the prospects of the Association and its cause for self-congratulation.

The address of the President, **Dr. Lewis Elsberg**, of New York, was read by the Chair.

The first paper in order was that of **Dr. Ephraim Cutter**, of Boston, entitled

THROAT SYPHILIS AND TUBERCLE, ACCORDING TO SALISBURY:

The paper was intended to show, first, how throat syphilis was distinguished from tubercle according to Salisbury; second, what syphilis was on the Salisbury plan; third, what tuberculosis was on the Salisbury plan; fourth, differential diagnosis; fifth, mode of conducting the physical exploration.

Dr. Carl Seiler, of Philadelphia, inquired as to the size of the spores, both in syphilis and tuberculosis, as well as to size of the filaments developed from these spores.

Dr. Cutter replied that he had not made accurate measurements of these, for he did not consider it necessary. All that was necessary for a differential diagnosis was to be familiar with the appearance of these in the two instances.

Dr. E. L. Shurley, of Detroit, next read a paper upon

THE TREATMENT OF PHARYNGITIS SICCA.

Of about two hundred patients, of all ages, under treatment for various diseases, both hospital and private, whose pharynges he had examined, nearly one-half presented the objective symptoms of pharyngeal or naso-pharyngeal catarrh, or follicular pharyngitis. Of these there were only three with well-marked appearances of pharyngitis sicca. Most of these cases were chronic, and occurred in persons of middle or advanced life. Therefore, Dr. Shurley thought that this morbid condition was neither always an ultimate stage of chronic pharyngeal catarrh, or follicular pharyngitis, nor an accompaniment of old age, nor a condition depending upon so-called scrofula, but a local change which depended not only upon previous disease of the mucous membrane, but upon some peculiar constitutional defect. He thought, therefore, that before any plan of local treatment was instituted, a very careful investigation of the vital status of the patient should be made, particularly of the primæ viæ, and a proper systemic treatment at once adopted. As aids to digestion, he had found cornin and xanthoxylin, alone or combined with an acid, to act the best. The tincture of calumbo and Fowler's solution were also highly beneficial in some cases; while in the subjects of malarial toxæmia the sulphate or phosphate of quinine was indicated. In those cases characterized by a constant deficiency or perversion of the hepatic and intestinal secretions he had found, in addition to general tonic treatment, the use of several large doses of ammonia mur. or soda phosphate to yield excellent results. Cod-liver oil and iodine were, of course, indicated in some instances, but great care was necessary in their use, lest by an unfavorable effect upon the stomach the greatest desire was defeated. Hygienic treatment and avoidance of all impure air was, of course, to be enjoined. Though the effects of local treatment were too often transient, it was not without benefit in almost all cases. Applications of iodine, nitrate of silver, sulphate of copper, petroleum oil, and the galvanic current had proved most beneficial in his hands.

Dr. Bosworth remarked that he had found this condition to frequently affect cigarette makers, and thought occupation had much to do with its causation. He had not found the condition to depend upon disturbances of the general health or stomach. He had never used galvanism in the treatment of his cases. He had been well satisfied with the use of drugs, especially with powdered blood-root.

Dr. Cutter considered the disease due to improper nourishment.

First Day—Afternoon Session.

The Association was called to order by the Chairman at 3.30 P. M.

SOME PRACTICAL SUGGESTIONS IN CONNECTION WITH THE USE OF THE LARYNGOSCOPE IN CHILDREN.

Dr. George M. Lefferts, of New York, read a paper upon this subject. He called attention to the special importance of the diseases of the larynx in children. The difficulties to be encountered were both moral and physical. With children, laryngoscopy was an art by itself, and required a special training of both manner and method. The most difficult cases to manage were those which had been subjected to unscientific and unskilful treatment. In cases where it was found necessary to proceed *vi et armis*, the best way was to envelop the child's body and arms with a strong towel, pinning it closely about the patient, and then place it upon an assistant's lap, the physician securing the child's legs between his knees. In this way an examination could readily be made.

The first essentials of success were, in children, a small laryngeal mirror and a perfect illumination. The first introduction of the glass, at a given sitting, was always the most successful. Acutely inflamed laryngeal parts and largely hypertrophied tonsils would often completely prevent examination. Screaming and crying, contrary to what may be supposed, was not a disadvantage. To see beyond or over the epiglottis it was necessary for the observer to stand or at least throw the child's head far backward and to carry his mirror well upward into the pharynx, and finally, if possible, to induce the child to phonate the vowel-sound "e" as loudly and quickly as possible. In the majority of cases of acute laryngeal disease in small children, a complete and satisfactory result was unfortunately seldom attained.

Dr. Cohen believed that in the majority of cases in which he had seen the larynx in very young children, it had been the result of a happy accident rather than skill. He generally allowed the nurse to hold the child.

Dr. Cutter cited a case in which he had diagnosticated an intra-laryngeal growth in a child two and a half years old.

The paper was further discussed by Drs. Mynter, Lincoln, Smith, Rumbold, Knight, Bosworth, and Lefferts.

The next paper was by **Dr. Beverley Robinson**, of New York, entitled,

SUGGESTIONS AS TO THE THERAPEUTICAL VALUE OF REST IN THE TREATMENT OF LARYNGEAL DISEASES.

Rest had been applied to laryngeal diseases in a somewhat imperfect and casual way. As specialists we were too apt to consider the vocal organ as something apart from the other organs of economy, and to overlook the first elements of therapeutical science in our efforts to relieve our patient, when in a painful state, from lesion of its tissues. In acute laryngitis the voice should be kept absolutely still, the respiration should be as quiet as perfect repose of body and mind would permit, and there should be no injudicious attempt made by the patient to use the voice, even for the smallest home concerns. In chronic laryngitis a problem of a different sort was offered. The main thing to be kept constantly in view was to change the static engorgement of the tissues into a more active circulatory condition, and then to watch and guide this to a normal state. The last traces of chronic congestion and thickening were slow to disappear, but here again physiological rest was almost the only reliable means of cure.

In nervous affections of the larynx rest by itself might be curative. Again, ulcerative phthisical laryngitis has been cured more than once by wearing a tracheal canula during several months, thus giving rest to the laryngeal tissues. In morbid growths of the larynx there was reason to believe that the rest afforded by tracheotomy would be serviceable. In cases of traumatic injury to the larynx, with or without subsequent œdematous infiltration, it was marvelous to note the good effects of tracheotomy, and consequently of rest to the larynx, and of freedom from irritating contact with air.

Physiological rest was often attainable by the employment of medicines topically applied within the larynx.

Whenever and wherever we were called upon to treat laryngeal troubles, we should bear in mind that the production of physiological rest was the curative principle upon which most of the good effects attributable to other means, medicinal, surgical, hygienic, in the main depended, and we should then be willing to give to it its genuine value.

Drs. Smith, Shurley, Bosworth, Knight, and Roe, concurred in the main with the views expressed by Dr. Robinson.

Dr. Seiler thought there should be a distinction made between those cases in which the vocal chords alone were affected, and those in which the muscles were affected. There was another class of cases in which real pain in phonation existed, and in these cases absolute rest was necessary.

Dr. Cohen agreed with Dr. Robinson in all except the performance of tracheotomy, with which he had very little experience.

Dr. Cutter inquired of Dr. Robinson if he performed the operation of tracheotomy without an anæsthetic.

Dr. Robinson replied that he did when possible.

The paper was still further discussed by Drs. Knight, Allen, Roe, Cushing, and Robinson.

Second Day—Morning Session.

The Association was called to order at 11 A. M., Dr. Cohen in the chair. The Secretary read the minutes of the business meeting of the last annual session.

By vote of the Association, Drs. W. Gleitsman, of Asheville, N. C., S. M. Langmaid, of Boston, E. W. Cushing, of Boston, Harrison Allen, of Philadelphia, C. E. Bean, of Louisville, C. E. Sajous, of Philadelphia, Wm. H. Daly, of Pittsburg, Pa., and William C. Jarvis, of New York, were elected active fellows.

Dr. Manuel Garcia, of London, was elected to honorary fellowship, and Dr. Carlo Labus, of Milan, was elected to corresponding fellowship.

The Committee on Nomenclature, Drs. J. Solis Cohen, F. I. Knight, Beverley Robinson, and Ephraim Cutter, was reinforced by two additional members, Drs. J. H. Hartman and Andrew H. Smith, and requested to continue in office for another year, in order to complete their work.

As the members of the American Laryngological Association had received an invitation to attend the first International Laryngological Congress, to be held in Milan the first week in September, 1880, it was resolved that the President should appoint three members as delegates to represent the Association in that Congress, and the Secretary be instructed to furnish said delegates with proper credentials.

Drs. Elsberg, Hartman, and Seiler were appointed delegates in accordance with the above resolution.

Upon motion, the *Archives of Laryngology* was made the official organ of the Association.

Dr. Thomas F. Rumbold, of St. Louis, exhibited an improved instrument for the removal of intralaryngeal growths, after which the Association adjourned.

Second Day—Afternoon Session.

The Association was called to order at 3.30 P. M., and, at the request of the Chair, Dr. F. I. Knight presided, while **Dr. J. Solis Cohen**, of Philadelphia, proceeded to read his paper on

PRIMARY TUBERCULOSIS OF THE LARYNX, WITH SPECIMENS AND MICROSCOPIC SECTIONS.

A detailed clinical history of a very interesting case of this rare affection was given, together with the carefully recorded results of the post-mortem examination of the same.

Dr. Seiler remarked that about three weeks before the death of the patient he had seen him at the dispensary, and although there were slight indications of lung disease, it was the very great change in the larynx which caused him to give a bad prognosis.

Dr. Cushing remarked that he had seen two cases of tuberculosis in the larynx, where he and other more competent observers could find no evidence of tuberculosis in the lungs.

Dr. Seiler thought that phthisical lesions could be detected in the larynx before there was any evidence of their existence in the lungs.

Dr. Roe instanced two cases which came under his notice last fall.

A somewhat lengthy and interesting discussion followed, in which Drs. Asch, Roe, Seiler, Robinson, Knight, and Cohen participated.

The next paper was by Dr. Frank H. Bosworth, of New York, upon

NASAL STENOSIS.

It was generally recognized that the successful treatment of nasal catarrh lay in the total abolition of that thickened or hypertrophied membrane which formed so prominent a feature of the disease; and by nasal catarrh in this connection he desired to limit himself to the ordinary chronic nasal catarrh, in which the prominent and characteristic feature was a hypertrophy of the mucous membrane lining the nasal cavity. In the vault of the pharynx the hypertrophy involved mainly the glandular structure. The characteristic appearances of all the parts involved were described in detail. The local application of nitric acid was a very good means of destroying the diseased tissue. The use of nitrate of silver was somewhat limited. The best method of applying it was by means of a flat probe, on one side of which had been fused a small bit of caustic. The doctor thought that acetic acid offered marked advantages, in its use, over most chemical agents. He had used this remedy in a large number of cases, and had rarely been disappointed in obtaining excellent results. Two or three applications were all that was necessary. It should always be borne in mind that the result of irritating local applications might be excessive inflammation, with the danger of its extending to the integument without. The galvano-cautery was thought to be least liable to cause excessive inflammation.

Dr. Rumbold remarked that he had for years used the scissors to remove the diseased tissue.

Dr. Shurley had not been satisfied with the use of chemical agents.

Dr. Allen alluded to the occurrence of erysipelas in hospital cases, but he had never known of its occurrence in private practice.

Dr. Lefferts protested against the prevalent use of the terms "stenosis" and "stricture" as applied to the nasal passage. Stricture was the narrowing of the calibre of a tube by contraction of its fibres, while stenosis was the narrowing of the nasal passage by relaxation of the mucous membrane.

Dr. Daly was in the habit of removing the hypertrophied mucous membrane with a galvano-cautery electrode at cherry-red heat.

Dr. Lincoln spoke in praise of the local application of chromic acid.

Third Day—Morning Session.

The Association was called to order at 10.30 a.m. by the Chairman.

Dr. Carl Seiler, of Philadelphia, proceeded at once to the exhibition of some improved instruments for the removal of intra-laryngeal growths, after which he read his paper, which consisted of the history of a case of

PAPILLARY GROWTH OF THE LARYNX.

The paper was discussed by Drs. Glasgow, Langmaid, Cohen, and Seiler.

The next paper was by Dr. J. O. Roe, of Rochester, N. Y., entitled

FRACTURE OF THE LARYNX.

An interesting history of a case with the post-mortem of the same was given.

There being no discussion upon this paper, the Secretary proceeded to read the paper of Dr. E. Fletcher Ingals, of Chicago,

ON THE SO-CALLED SWALLOWING OF THE TONGUE.

This occurred most commonly in children.

Dr. Cohen considered the expression "swallowing of the tongue" an improper one. He cited a case which had come under his notice, where the patient complained of his tongue flopping up against the roof of his mouth, and which was relieved by a drink of brandy.

The prescribed programme for the morning session having been completed before the hour of adjournment, upon motion, Dr. Langmaid, of Boston, was requested to read his paper which proved to be an exceedingly interesting, able, and important dissertation on

THE TREATMENT OF CERTAIN FORMS OF VOCAL DISABILITY BY THE APPLICATION OF THE PRINCIPLES OF VOICE CULTURE.

Attention was especially called to two points: one was that artists depend quite as much upon flexion of tone as upon any other means for the production of effect; the other was that the force of blast in voice would surely give out.

Dr. Seiler expressed his great gratification with the paper, inasmuch as he had done a great deal of work in the same direction since 1858. He had demonstrated anatomically that there was such a thing as marginal vibration of the cords. He could not coincide with Dr. Langmaid in saying that the so-called false register was a false voice. The chest voice had a full sound; the falsetto had a weak sound. In falsetto the margins of the vocal cords were relaxed, and, with proper cultivation, a sound could be produced by these marginal vibrations which would favorably compare with the notes of the chest, and by the laity could not be distinguished from them.

Third Day—Afternoon Session.

The Association was called to order at 2.30 p.m. by the Chairman, Dr. Cohen.

NASAL POLYPUS.

Dr. William H. Daly, of Pittsburg, Pa., read an interesting paper upon this subject, which was discussed by Drs. Allen and Knight.

Dr. William C. Jarvis, of New York, read a paper on

THE SURGICAL TREATMENT OF HYPERTROPHIC NASAL CATARRH.

He began by stating that chronic nasal catarrh had for its invariable concomitant an hypertrophy of the tissues over the turbinated bones. That hypertrophy was found to involve the posterior much more frequently than the anterior extremities of the turbinated tissue. He adduced several histological and pathological specimens to illustrate this tendency. Stenosis was divided into anterior and posterior varieties; the latter being of greater importance, its treatment was detailed without reference to the former. A new wire snare écraseur, devised for the removal of the hypertrophied tissue, was exhibited, as well as several other new instruments used in the treatment of these cases.

Dr. Andrew H. Smith brought a patient before the Association who presented a well-marked substernal tumor which had been diagnosticated as such by Dr. Clark five years previous. Its nature was not known.

Dr. Beverley Robinson presented the history of a case in which great dyspnœa seemed to be attributable to hypertrophy of the tonsils.

Dr. S. H. Chatman, of the Yale School of Medicine, exhibited a portion of the body of the third cervical vertebra which he had removed from the throat of a male patient in January. The cause of the necrosis was unknown.

At the private business session which followed, the following officers were elected for the ensuing year: *President*, Dr. J. Solis Cohen, Philadelphia; *Vice-President*, Dr. W. C. Glasgow, St. Louis; *Secretary* and *Treasurer*, Dr. Geo. M. Lefferts, New York.

The Association adjourned to meet in Philadelphia in 1881, on the Monday following the meeting of the American Medical Association.

Correspondence.

CONTINUOUS ELASTIC DILATATION OF UTERINE CAVITY.

To the Editor of The Medical Record.

Sir:—I have just been reading your report of the meeting of the American Medical Association, and there I find a brief note of a "New Uterine Dilator," by Dr. Marcy, of Massachusetts. As priority of publication in such matters is sometimes of importance, I think it well to point out that many months ago I published in the *Lancet*, and showed to the Obstetrical Society of London, an instrument for dilating the uterus by continuous elastic pressure. The apparatus is fully described in my book on "Diseases of Women," recently published by Messrs. Wood & Co., of your city, and it will be found to supersede entirely all kinds of tents for every purpose of uterine dilatation. I am, etc.,

Lawson Tait.

Birmingham, Eng., June 23, 1880.

PHYSICIANS AND DRUGGISTS.

To the Editor of The Medical Record.

Sir:—I do not agree with your correspondent in his strictures on incompetent druggists. It is, in the first place, impossible to go back, in large cities at least, to the old plan of compounding your own medicines, and, in fact, it would be a greater evil than that now complained of, unless the prescriber intends to depend on homœopathy. No one but a thoroughly trained apothecary can properly make up compound prescriptions.

The remedy, it strikes me, lies in this: let every physician pick out a *reliable* druggist in certain sections of the city, where his practice lies, and *insist* on his patients going there and nowhere else. He has a right to prescribe the apothecary as well as the medicine. There are plenty of reliable druggists. Then it would be better that physicians should be more careful about writing their prescriptions—the Latin, the abbreviations, and the chirography—and not *abbreviate* too much. Now I contend that * * * might have written his prescription more plainly, if not more correctly, as thus:

℞. Tinct. opii camph.	ʒ iv.
Potassii nitratis	gr. cxl.
Syr. tolutan.	℥ ij.
Aquæ cinnamo*mi*.	q.s. ad ℥ iv.

M.

There could then be no room for doubt as to the meaning of the directions.

It would be almost as reasonable to contend that people should be their own physicians, because there are so many quacks, and the law draws no distinct line of demarcation between the regular and the irregular. But, as a general rule, there is a way of distinguishing the one from the other. Generally speaking physicians pay too little attention to the character of their druggists and the purity of the drugs they use. By dealing with two or three only in a large city, or one in a small town, the physician can gradually ascertain the degree of his competency, his prudence in his intercourse with patients, and the reliability of his drugs. "Suum Cuique."

SANITARY MATTERS IN JAPAN.

To the Editor of The Medical Record.

Sir:—The National Health Board reports the reappearance of cholera in several sections of the empire within the last month. As the number of cases has been not more than three (3), even in those sections which suffered most last year, I am disposed to think that few, if any of them, are true cholera, as I have seen two cases of congestive malarial fever within the last week, which might be easily mistaken for cholera, by even better diagnosticians than nine-tenths of the Japanese doctors. The wonder is that, with the sharp lookout kept for the return of the disease, there have been no more reported.

Be this as it may, we have every reason to congratulate ourselves with this next to complete exemption from the scourge so far, as last year, by this time, several hundred cases had occurred in each of the localities of its subsequent greatest prevalence.

Preparations on a large scale have been made for its expected return, however, especially in the purchase of carbolic acid, the customs returns showing that over 1,000,000 pounds have already arrived from Europe and elsewhere. As it is, for the most part, in one-pound bottles, and of fairly good quality, it necessarily represents a no inconsiderable sum. It is to be hoped the speculators in the article will be disappointed in their expected gains, based on the repetition of the calamity of last year. The lesson of the last three years, though a severe one, has been productive of much good, in awakening the whole country to the necessity of adopting sanitary measures of all kinds, public and private. The great question of a pure drinking-water supply is receiving its share of attention. It will take many years, however, before any great changes can be brought about in the habits and customs of the mass of the people, so long entirely ignorant of many of the most primitive hygienic laws. We are safe in saying, however, that more progress has been made in sanitary science during these three years of epidemic cholera than could have been attained in a quarter of a century of the best directed efforts under less disastrous circumstances.

Every prefecture throughout the empire has now its sanitary bureau, under the direction of intelligent officers, as a part of its organization, whereas, three years ago, only one existed at the capital.

The question of cheap and quickly available disinfectants is one of vast importance to the country, as the time required to bring them from Europe, added to the great expense, has not only been a serious obstacle to their use in quantities sufficient to be effective, but is likely to be again in any sudden outbreak of the disease. As carbolic acid cannot be made here except in very small quantities, because of the few gas-works in operation, I have suggested to the government the use of sulphurous acid (sulphuric acid being manufactured here in considerable quantities), so highly recommended by Lebert "Ziemssen's Cyclopedia," in vol. i., page 452.

This suggestion was adopted by this prefecture during the epidemic of 1877, when carbolic acid ranged from $1.25 to $5.00 per pound. It was given a fair trial by its exclusive use in one of the worst sections of Yokohama, as to its hygienic condition, with apparently the best results, as it almost entirely escaped the disease raging elsewhere.

D. B. SIMMONS, M.D.,
Chief Surgeon to Ken Hospital.

YOKOHAMA, JAPAN.

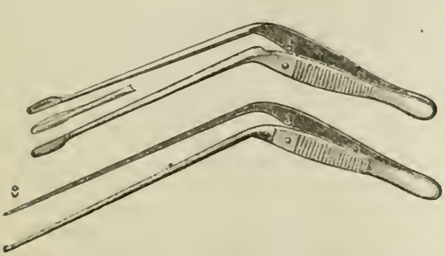
New Instruments.

SOME NEW AURAL INSTRUMENTS.

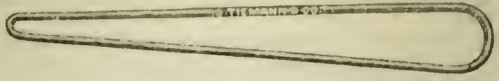
By SAMUEL SEXTON, M.D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

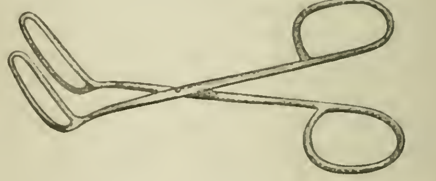
THE writer, requiring for his own use some aural instruments of much lighter make than usually to be found in the cutler's collection, the following were manufactured at his request. Their continued use for some months has satisfied him that their delicate construction has not been at the expense of their usefulness, a fact of no little importance when it is considered that in many operations on the ear (especially for the removal of foreign bodies from the meatus externus) one is prone to resort to more vigorous efforts than the case requires.



The cut shows two kinds of forceps about one-third smaller than the instruments themselves. These forceps have a very firm bite and close with much precision—points that are obtained from the accurate workmanship, and from the shortening of that part of the instrument held in the fingers when in use. One of them has broad and smooth ends, not liable to injure the meatus or membrana tympani, and is suitable for the removal of foreign bodies; the other has fine points, with sharp teeth set at a right angle, and is of service in removing smaller objects. Being more slender it can sometimes be inserted so as to grasp an object where other forceps would push it further into the meatus. These forceps have but little or no claim to originality in shape, but they are recommended especially for their light and delicate construction.

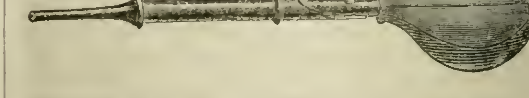


The oroscope here figured is, so far as it is known to me, new in design. It is especially adopted to aid in explorations of the mouth and throat; for the former it seems to be all that is desired, and for purposes of tongue depression it is usually quite effective in affording a good inspection of the throat, although, for the latter purpose, it is not intended to take the place of the more elaborate instruments in use when the case requires their employment. The buccal cavity can be thoroughly examined by the use of the oroscope; and daily experience teaches me that reflected neuralgias are so frequently a cause of aural disease that a careful examination of the teeth, etc., is necessary in all cases. Either end of the oroscope can be used in the mouth, thus providing a suitable tongue depressor for the examination of children, the smaller end being adapted to the smallest mouth. I have observed that children do not object so much to its use as they do to that of spoons or the formidable tongue depressors in ordinary use. The instrument is inexpensive, easily cleaned and polished; it is less than fifteen centimetres in length and at the larger extremity two centimetres wide. It is well adapted to a pocket-case.



This nose speculum is very light, and unlike many others is provided with handles through which the thumb and forefinger can be thrust, giving it more precision than when held loosely, and permitting of the distention of the nares to the required extent in a gradual manner, the speculum opening as the handles are separated. This natural motion of the fingers, acquired by every one in using scissors, seems to me a better one than the contrary movement generally required by other instruments.

Specula opening by a spring are painful if by chance they are allowed to expand suddenly, thus alarming children and the more sensitive adults. The instrument is made of steel, is very light, and can be packed away in a small space.



The aural powder insufflator consists of a vulcanite barrel which is composed of two parts, one of which is used to scoop up the powder, the other is provided with a small soft-rubber bulb for driving out the powder, and has a valve that prevents the powder being drawn back into the instrument after its expulsion. When these two portions are fitted together their appearance is as shown in the figure. I much prefer to puff powders into the external auditory meatus in this way to blowing them out of an instrument with the mouth. The instrument is about twelve centimetres in length. These instruments were made by Geo. Tiemann & Co., to whom much credit is due for their excellent quality.

◆

AN IMPROVED MICROTOME.

Two Hundred Sections a Minute, each $\frac{1}{1200}$ of an Inch in Thickness.

By WM. HAILES, M.D.,

PROFESSOR OF HISTOLOGY AND PATHOLOGICAL ANATOMY, ALBANY MEDICAL COLLEGE.

I wish to present to the notice of the profession an instrument designed especially for use in the working laboratories of our medical schools and colleges, where large numbers of sections are required for microscopical examination.

It occurred to me several years since that a microtome could be devised, combining, in a single instrument, many of the advantages existing in other instruments, and I published an article entitled "Sections and Section Cutting," in the *American Journal of Insanity*, April, 1879.

This instrument, greatly improved, together with examples of its work, I present for examination.

It may be employed as a simple instrument or as a freezing microtome, arranged either for ice and salt, ether spray, rhigoline, etc.

The employment of ice and salt (coarse) is preferred, because it costs but little and freezes the mass solidly and quickly, and, if desired, 500 or 1,000 sections can be obtained in a few moments.

Time of freezing is about seven minutes, except in very warm weather, when it requires a few moments longer.

The instrument does not work quite so satisfactorily in very warm weather, owing to the rapid melting of the surface of the preparation.

It is absolutely necessary that the mass should be frozen solid, or the sections cannot be cut smoothly.

An extra freezer may be employed, and while one specimen is being cut the other is being frozen, and by exchanging cylinders (they being interchangeable) no delay is necessary to its continuous operation.

The art of cutting is readily acquired, and when the preparation is frozen it is the work of a few moments to obtain several hundred sections. Two hundred or two hundred and fifty sections can be made each minute, and of a uniform thickness of $\frac{1}{1200}$ of an inch (or thinner). The delicacy, ease, and rapidity with which they can be cut must be seen in order to be appreciated It is not necessary to remove the sections from the knife every time, but twenty or thirty may be permitted to collect upon the blade. They lie curled or folded up upon the knife, and when placed in water, straighten themselves out perfectly in the course of a few hours. The knife I employ is an ordinary long knife, from an amputating case.

Perfectly fresh tissues may be cut without any previous preparation, using ordinary mucilage (acaciæ) to freeze in, but most specimens require special preparation.

If preserved in Müller's fluid alcohol, etc., they require to be washed thoroughly for several hours, and then, according to the suggestion of my friend, Dr. David J. Hamilton, F.R.C.S.,* etc., of the University of Edinburgh, Scotland, the specimen is placed in a strong syrup (sugar, two ounces; water, one ounce) for twenty-four hours, and is removed to ordinary mucilage acaciæ for forty-eight hours, and is then cut in the freezing microtome.

These sections may be kept indefinitely in a preservative fluid recommended by Dr. Hamilton: ℞. Glycerine, aqua destil. āā ℥ iv.; acid. carbolic., gtts. iij. Boil and filter. The addition of alcohol, ℥ ij., is advisable.

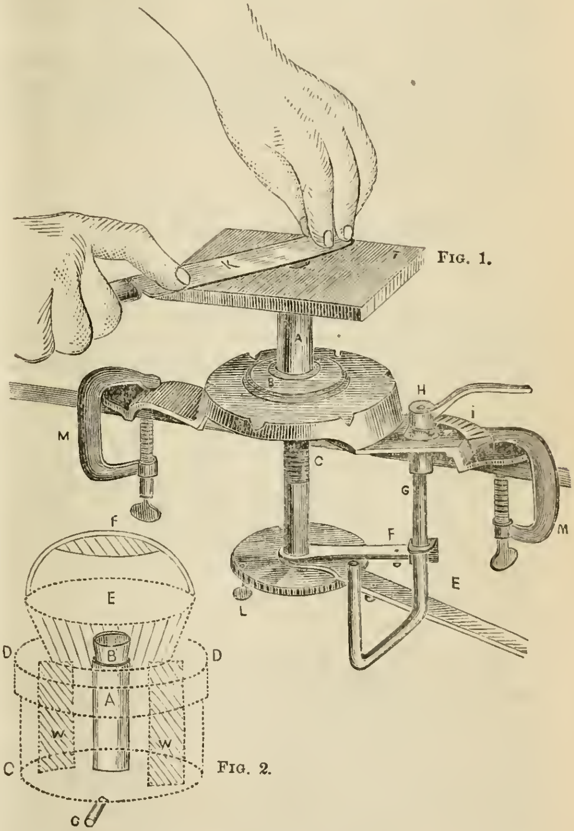


FIG. 1.

FIG. 2.

Fig. 1.—Poly-microtome (without freezing apparatus). A, small well fitting on pyramidal bed-plate; B, pyramidal bed-plate containing different sizes; C, micrometer screw; D, ratchet-wheel attached to screw; E, lever actuating the micrometer screw by means of a pawl engaging in teeth of ratchet-wheel; F, arm carrying a dog, which prevents back motion of screw; G, regulator for limiting the throw of lever, and consequently governing the micrometer screw; H, lever nut for fixing regulator; I, index, with pointer and graduated scale, from $\frac{1}{2400}$ inch to $\frac{1}{200}$ inch; K, knife for cutting sections; L, knob to turn micrometer screw direct when pawls are detached; M, table clamp; T, table of microtome, with glass top to facilitate cutting.

Fig. 2.—A, B, tube contain'ng specimen which is surrounded by freezing mixture in tin receiver C, D; E, F, revolving hopper with wings; W, W, for stirring the ice: G, outlet for melted ice.

◆

Ethidene-dichloride has been given by Dr. J. T. Clover 1,877 times without a fatal result. In his 1878th case, however, the patient died. Autopsy revealed a fatty heart.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 11 *to July* 17, 1880.

Simons, J., Lieut. Col. and Surgeon. Granted leave of absence for one month. S. O. 118, Dept. of the East, July 15, 1880.

Winne, C. K., Capt. and Asst. Surgeon. Assigned to temporary duty at Ft. Brady, Mich. S. O. 116, Dept. of the East, July 12, 1880.

Price, C. E., Capt. and Asst. Surgeon. Granted leave of absence for two months with permission to apply for two months' extension. S. O. 154, A. G. O., July 15, 1880.

Comegys, E. T., Capt. and Asst. Surgeon. Granted leave of absence for one month, on Surgeon's certificate of disability, with permission to go beyond limits of the Department. S. O. 135, Dept. of Texas, July 8, 1880.

"Songs of the Cranial Nerves" is a pamphlet of fifteen pages, and forms a novel contribution to anatomical mnemonics. Each of the cranial nerves is down in rhyme and set to various popular tunes, such as "Marching through Georgia," "Captain Jinks," "Auld Lang Syne," etc. Much labor and ingenuity have been shown in reducing the descriptions to meter and rhyme, and the author has certainly succeeded very well. The cranial nerves are the bane of the medical student, and as rhyme can always be more easily remembered than prose, the present verses will be likely to help the learner very much.

Determination of Sex in Utero.—We are in receipt of a letter from Dr. J. C. Kendall, of Norwalk, Conn., in regard to this subject. He states that of the various theories which have been proposed in the past three years, none are at all satisfactory, and the subject remains very nearly in *statu quo.* The history of some families seems to indicate that there is some law, however, else why are there only males in one family and only females in another. Dr. Kendall questions very seriously whether the theory of different degrees in height of orgasm has anything to do with determining sex. The sperms and ova are all prepared before coition, and the height of orgasm could scarcely affect them.

Then as regards the theory that the time of coition relatively to menstruation has something to do with determining sex, how on this hypothesis can we explain the variation in sexes in cows who are always brought to the bull as soon as heat begins. Furthermore, Dr. K. has known of cases in which a sheep always produced offspring of a single sex; and of a bull who was famous for always producing heifer calves; in so much so that a female was almost guaranteed by the owner.

Dr. Kendall asks for further light upon the subject. This unfortunately cannot be given for the simple reason that no one yet knows how the sex is determined. The fact that will probably be most widely accepted in regard to the matter is, that vigorous parents are more likely to have male offspring. It is very rare to find a physically weak couple who have a family of males. It is not likely, however, that any single thing determines the sex, it is the result of a number of factors which we are yet far from knowing.

Further Anatomical Uses of the Cat.—In an article in *Science*, by Prof. Burt G. Wilder, entitled "A Bit of Summer Work," the question of how to employ profitably some of the summer vacation is discussed and a suggestion in answer made. The brain, says Prof. Wilder, is not only the organ least satisfactorily treated in text-books, but at the same time the one concerning which the most should be known, from the double stand-point of physiology and psychology. This objection, however, is generally raised: that it is very difficult to get human brains to dissect, and that from these alone can one get a knowledge of man's cerebral structure. So far as this proves the fact, that from a single animal brain, perfectly fresh or well preserved, more may be gained than the average medical student learns from the human brains usually examined in the dissecting-room. This is due to the fact that, excepting the absence of the occipital lobes of the hemispheres, the brains of the cat, the dog, the rabbit and the sheep, present nearly all the structural features of the human brain, while their smaller size and greater accessibility better adapt them for manipulation. Of these animals the brain of the cat is on the whole the most available. Descriptions of the brain of the dog, the sheep and rabbit are given in the little works of Morrell, Foster, and Langley.

Influence of the Moon on Death.—*Just before the new moon.*—Camden died in 1623, a day before the new moon; Harvey in 1657, a few hours before; Milton in 1674, two days before; Newton in 1726, two days before; Whitfield, in 1770, a few hours before; Dr. Warren, a day before. *Just at the new moon.*—Henry Jenkins died at the age of 169, on the day of the new moon; also Elizabeth Stewart, aged 124. It is to be hoped that no one will doubt these ages merely because they are not fully proven. *Soon after the new moon.*—William Leland, aged 140, died on the day after the new moon; John Constant, aged 113, two days after; George I. in 1727, three days after; Sterne in 1768, two days after; Garrick in 1779, three days after; Dr. Johnson in 1784, two days after; Dr. Franklin in 1790, three days after; Sir Joshua Reynolds in 1792, one day after. *On the first quarter.*—Chaucer died in 1400, on the day of the first quarter; also Henry VIII., in 1547; also Cornaro, in 1566; Wilkes in 1797; while Rousseau died in 1778, one day after the first quarter. *Just before the full moon.*—Cardinal Richelieu died in 1642, three days before the full moon; Sydenham in 1689, two days before; also Locke in 1704; Louis XIV. in 1715, a few hours before; Marlborough in 1722, two days before; Linnæus in 1778, two days before;

Sir William Hamilton a few hours before. *Just after the full moon.*—Thomas Parr died, aged 152, two days after the full moon; John Effingham, aged 144, two days after; also Elizabeth Hilton, aged 121; Luther in 1546, three days after; Calvin in 1564, two days after; Shakespeare in 1616, one day after; Vandyke in 1641, two days after; also Oliver Cromwell; also Queen Anne in 1714; George II. in 1760, one day after; Lord Guilford in 1722, three days after; and Washington, three days after. *At the full moon.*—Swedenborg in 1772, on the day of the full moon; also the Earl of Chatham in 1778; Burke in 1797, on the very instant of the full moon. *Last quarter.*—Copernicus died in 1543, on the day of the last quarter; also Queen Elizabeth, in 1603, while Bacon died in 1676, one day after.

Dr. Mosely says: "Here we see the moon, as she shines, like the sun, on all alike while living, so she makes no distinction in her influence on the dying, a few millions of whom pass away every day in the year, some before, or after, or at every change of the moon."

A SUCCESSFUL CASE OF LITHOLAPAXY, FOLLOWED BY ADHERENT STONE.—Dr. R. F. Dyer, of Ottawa, Ill., sends us notes of the following case: A patient, aged thirty, had suffered from stone in the bladder for several years. He was operated on last August by Dr. Dyer. Chloroform being given, the Bigelow lithotrite was passed, and a stone, measuring one and a quarter inches, was at once seized and crushed. The operation lasted one hour and three minutes, reckoning from the time when the anæsthetic was administered. Several small stones were passed through the catheter. The patient resumed his work in a few days, and continued it until May 2, 1880. He then presented himself again, and was discovered to have a small stone adherent to the left side of the bladder, about two inches from the internal orifice of the urethra. The stone was after some effort detached. A few days later the patient was again etherized, the stone crushed, and the débris washed away. The time consumed was just twenty minutes. The patient resumed work two days later and has not complained since. The stone last crushed was one-quarter of an inch in diameter. Dr. Dyer queries whether it was not a splinter of the first operation.

A CASE OF HYDATIFORM MOLE.—Dr. W. H. Sharp, of Volcano, W. Va., writes to us of a case of hydatiform mole occurring recently in his practice, which had some peculiar features. The patient was a delicate woman, single, and twenty-one years of age. For three years she had not been well, but had suffered from scanty menstruation, and eighteen months before had had hysterical convulsions. For the previous year she had felt a lump in her abdomen; four months before, after exposure to cold and wet, she became dropsical. On seeing her January 16th she was extremely anæmic and dropsical, passed but little urine, and that was one-fourth albumen. There was scanty menstruation at the time. Under diuretics, cathartics, and jaborandi, the dropsy disappeared, but a slight metrorrhagia continued. No casts were found in the urine. February 3d, the patient passed per vaginum a large mass of hydatiform moles.

The areolæ of the nipples were noticed to be enlarged and darkened. Ergot and iron were given. On February 20th a vaginal examination showed the uterus enlarged, os patulous, some hemorrhage, and a discharge of glairy mucus and cysts took place. Tr. iodine co. was freely applied to the cavity. Twelve days later a large amount of the cysts was scraped away with a copper wire curette. During the succeeding weeks the compound tincture of iodine was frequently applied. The uterus gradually returned to its natural size. For the past two months the patient has been restored to health, and has menstruated freely.

The case is curious from the long retention of the mole—probably over two years—and the profound impression its presence made upon the system.

THE AGES OF PHYSICIANS IN NEW YORK CITY.—Dr. S. A. Hills, of this city, sends us the following interesting note:

In looking over your notice of the "Medical Register," by Dr. Wm. T. White, I was led to examine the list of physicians in New York City there given. Perhaps the result may be of interest to some of your many readers, who may not have the "Register" at hand.

Of the 1409 names there given, I find the patriarch of the profession to be Dr. James Anderson, a graduate of the College of Physicians and Surgeons of New York in 1820, and nine others whose graduation antedates fifty years, viz.: Dr. Geo. Lindsay, Joseph W. Richards, James O. Smith, in 1825; Dr. Joel Foster, 1826; James O. Pond and A. C. Post, 1827; Oliver P. Hubbard, 1828; Jared Linsly and Ovid P. Wells in 1829.

In the next decade, from 1830 to 1840, I find 61 names, among whom are found some of our New York's best known and honored physicians, viz.: Drs. Parker, Flint, Clark, Hamilton, Detmold, Wood, Sims, and many others, Drs. Parker and Detmold being graduates of 1830. The next ten years, 1840 to 1850, 97 names, and here, too, we find the names of many well known to fame. Between 1850 and 1860, 198 names whose hairs do not indicate life's work done. The next decade, 1860 to 1870, 371 names, all supposed to be in prime working order. From 1870 to 1880, 599 names, and 48 of the newly made graduates of 1880.

It will be seen that the last ten years has added largely to our numbers, and the last half of this period, nearly one-third of the entire number.

There are a few names whose date of graduation is not given.

The list contains the names of 15 female physicians. Dr. Emily Blackwell leads in priority, having graduated in 1854. All but two, graduates since 1870, and mostly from the Woman's Medical College of New York.

FOUL AIR IN THE PUBLIC SCHOOLS.—One of the teachers in the Twenty-fourth Ward died recently, it is said, of malarial fever, contracted by her in the school-house. The same disease has prostrated or seriously weakened nearly all the teachers in the primary department of the same school, and some of the children are suffering from it.

NERVE-STRETCHING AS A REMEDY FOR SCIATICA.—Dr. Jas. P. Bramwell reports, in the *British Medical Journal*, five cases of sciatica successfully treated by stretching the nerve. Dr. B. considers that when sciatica is due to a rheumatic inflammation of the nerve itself (which is its most frequent cause), stretching will be quite sure to relieve the trouble. His theory is that there is often an adhesive neuritis which binds the sheath to the nerve. The stretching breaks up these adhesions. The counter-irritation produced by the operation is also of benefit. The operation sometimes has to be repeated.

Medical Collection Agency Fraud.—A correspondent from Providence, Rhode Island, writes: "Permit me to inquire if others besides physicians in Providence have not been wheedled out of a moderate membership fee in what has proved to be a bogus collection agency, by the very plausible and modest Mr. ——, who visited this city last fall and winter, showing large lists of physicians who had subscribed to join such an agency, provided others, to the number of a hundred or so, would join, and promising, in return for the membership fee, to keep them permanently supplied with the combined delinquent lists of the membership, and to collect all bills placed in his hands for a very fair percentage. He issued one list here, and decamped, leaving part of a large lot of bills with an attorney here, who was wheedled into taking them, and leaving other bills for large amounts unaccounted for. I must add, for my own credit, that the bills of mine that he took were of little worth; but the point is that he kept them. He showed us a list of New Haven physicians who were delighted with the plan, etc., and I am informed that he left that place without even furnishing a single list of delinquents. He had also established agencies in Hartford, Portland, and other cities, and their names on his paper gave him a quasi endorsement that quite deceived us. As your paper goes everywhere, it may circumvent his further fraud."

Dr. Buchanan at Liberty.—The notorious Dr. Buchanan, of Philadelphia, of bogus diploma fame, of whose arrest mention was made in a recent number of the Record, has been released from prison, after furnishing bail, to appear for trial, in the sum of $12,000. The bail originally required was $5,000 in the United States Courts, and $6,000 in one of the County Courts, but when this was finally obtained he was obliged to give $1,000 additional bail on account of two indictments, which were found against him some years ago, and on which the bail was forfeited by his disappearance. It looks at present as though the successful career of the Professor was to be brought to an untimely end. Still this prompt and efficient action of Justice may be followed by a period of inertia, of which the wily diploma seller will doubtless make good use. If any one of the incorporated medical bodies of Philadelphia would devote a few hundred dollars to retaining a legal adviser to keep watch upon the matter, the conviction of Buchanan would now be insured.

Health of the City.—The temperature in the city, although still high, has ceased to be excessive, and the mortality has in consequence gradually diminished, as the following table shows:

	Deaths.	Infants.	Max. Temp.
July 13	127	52	87°
July 14	117	72	89°
July 15	98	70	81°
July 16	116	61	87°
July 17	97	52	81°
July 18	97	53	80°
July 19	79	..	..
July 20	122	..	..
Total	853		

The total mortality for the previous week was 915. The total mortality among infants for the week ending July 3d was 804; that for the week ending July 17th, was 450.

Dr. Tanner's Fast.—The 23d day of Dr. Tanner's alleged fast was completed on July 21st. The experimenter was then in excellent condition and suffering very little. On the sixteenth day he began to drink water freely, and his condition at once greatly improved. The physiological facts connected with the past week, so far as they can be obtained, are presented in the accompanying table:

Day of Fast.	Weight. Lbs.	Amount of water drank. Fl. oz.	Urine passed. Fl. oz.	Sp. grav. of urine.
16th	132	32	19¾	1022
17th	133½	66	23¼	1018–20
18th	137½	58	36¾	1023
19th	136½	36½	21	1011–12
20th	135	43½	46	1002–10
21st	135	48½	42½	1005–6
22d	134	34½	38¼	1001–10
Total		319	226½	

Dr. Tanner has had no passage from the bowels since the first day of his fast. His temperature, pulse, respiration, and skin have been normal. Assuming then, the fact given by Valentin and other physiologists, that as much water is lost by the lungs and skin as by the kidneys, we reach the following interesting paradox: During the first four days after the faster began to take water, he took into his system 192½ fluid ounces of water; he lost, by the kidneys 100¾ fluid ounces, and by the skin and lungs (assuming the usual physiological changes) an equal amount, or about 200 fluid ounces in all. Yet he gained in bodily weight during that time 4½ pounds! Calculating upon the data for the seven days, above recorded, a similar difficulty is found. The supposition that the whole thing is a farce is at once suggested. There are, however, three sets of watchers with him all the time; a regular physician, a *Herald* reporter, and an eclectic. One estimate of the urea in the urine gives: on the first day, 29 grammes; the fifth day, 16 grammes; 18th day, 14 grammes.

Ice for the Sick.—An excellent charity has been initiated by the St. John's Guild. It consists in supplying ice to the sick poor. Tickets are given out to the Assistant Sanitary Inspectors and the doctors at the dispensaries for distribution.

Dr. Lyon Playfair, M. P., leaves England for this country August 12th.

TRACHEOTOMY IN CROUP:

WITH REMARKS ON

THE PATHOLOGY, DIAGNOSIS, PROGNOSIS AND TREATMENT OF THE DISEASE, AND THE CAUSES OF DEATH IN FATAL CASES; WITH A REPORT OF THIRTY-FIVE OPERATIONS.

By JOHN H. RIPLEY, M.D.,

SURGEON TO CHARITY HOSPITAL: PHYSICIAN TO ST. FRANCIS' HOSPITAL, NEW YORK CITY.

PART V.

General Treatment.—Some authors recommend the discontinuance of all medication *as soon as tracheotomy has been performed;* but I suppose this advice is intended to apply to those cases only in which there is no serious constitutional disturbance; for, if there be any remedy which exerts a curative influence over the disease, it should certainly be continued after the operation. Is there any such remedy? I have already expressed my own belief to the contrary. Whenever any treatment of real value is discovered, the profession are not slow to adopt it. Indeed, the majority of physicians are only too willing to follow the advice of Dr. Clark to his students in regard to new remedies: "Gentlemen, use them while they cure." The best proof that no one plan of treatment now in use is very much superior to many others, is the fact that among practitioners there is no uniformity of treatment.

By a large and intelligent vote the profession have decided to pretty much give up the use of *calomel* in diphtheria, except as a cathartic, and yet there are a few who still believe it to be a specific in this disease, and furnish, from time to time, their quota of well attested cases which have been cured by its early and free use. *Bromine*, which was highly recommended for its supposed specific effect on the poison of diphtheria by a distinguished teacher of medicine in this city twenty years ago, was subsequently abandoned by its advocate as of no special value. His partner said to me a few months ago: "We found, after a more prolonged trial of this drug, that we lost just as many cases with it as without it." More recently it was again brought to the notice of the profession as a specific in diphtheria by a prominent therapeutist, but it has not now many advocates. If given in the large and frequently repeated doses deemed necessary in order to get its full beneficial effect, it will not long be tolerated by most stomachs, and this is a serious objection to its use; for, when once the stomach is disordered in this disease, it often remains weak and irritable throughout the sickness, and nutrition cannot thereafter be maintained. Still, if it would cut short the disease, this objection should not prevent its being used. I have given it a pretty fair trial, with negative results. Friends of mine have resorted to its use with the same unsatisfactory experience. Quite an amusing incident connected with this subject occurred in a hospital a few years ago. It shows the danger of attributing to drugs effects for which they are not in the slightest degree responsible. A young man was admitted into my wards suffering from a severe attack of diphtheria. His pulse was 150 and temperature 105½°. His tonsils, soft palate, and pharynx were covered with a thick, dirty-gray membrane. Both nares were plugged with membrane, so that he was compelled to breathe entirely through the mouth. He had been sick two days, and had not been under treatment. I said to the house staff: "We will give this man bromine and see whether we observe any marked effect from it." The following prescription was given to the apothecary:

℞. Brominii,
Potassii bromidi....āā ʒ ss.
Aq. cinnamomi....... q.s. ad ℥ iv.
M. S.—Teaspoonful, in milk, every two hours.

The progress of the patient toward recovery was most rapid and satisfactory, and began at once. On the third day after his admission I saw him a second time. The membrane had nearly disappeared from the fauces and nose—although no local treatment whatever had been used—his temperature and pulse varied little from normal, and his appetite was returning. I called for the bottle which was "curing" him. It contained an almost colorless fluid with a whitish sediment. The odor of bromine was exceedingly faint. A simple explanation followed. The druggist, not being acquainted with the physical properties of this medicine, had opened the tin can containing the bromine bottle buried in plaster-of-Paris, and had mistaken the packing for the "specific." As there was no indication for changing the treatment, it was continued for a couple of days longer, when the patient was discharged "cured."

"The chlorine mixture" (made by putting eight grains of chlorate of potassa into a strong pint bottle, pouring upon it a drachm of strong hydrochloric acid, corking the bottle until the violent action ceases, and then adding water, ounce by ounce, corking and agitating after each ounce, until the bottle is full), had at one time a great reputation for curing both scarlet fever and diphtheria. My first knowledge of it was obtained from a professor of surgery of this city, nearly twenty years ago. He spoke of having seen it used with great success in his native town during a terrible epidemic of diphtheria, in which no other treatment seemed to be of any avail. Having myself just come from a village where this dread disease had prevailed with fearful mortality, even in some instances sweeping off whole families, I treasured up the knowledge of this wonderful mixture for future use. My first experience with it, a few years later, led me to believe that it was, indeed, a sovereign remedy. Nearly all the patients that I treated with it recovered. If now and then one died, an explanation was easy and plausible. Either I did not see it early, or my directions were not carried out, or some inconsequential complications changed the result. I remember well a family of four small children that I treated successfully with this mixture. They all had naso-pharyngeal diphtheria and swollen necks. Wherever there occurred a little abrasion of skin or mucous membrane, there also soon appeared a diphtheritic membrane. They lay listless and apathetic for several days, breathing only through the mouth. Great difficulty was experienced in inducing them to take medicine or nourishment. Brandy, milk, beef-tea, and the mixture were given internally. The noses were syringed out twice daily with a solution of salt and water. All recovered, and all were subsequently more or less paralyzed. Was it the specific that cured them? I thought so then, but I do not now. After using this preparation for nearly two years, I came to the conclusion that, as a specific, it was a failure. Fatal cases occurred under its use, even when abundant time was given for it to act, and there was no special reason why it should not cure. I saw equally good results with other drugs in the hands of other doctors. It was a strong and unpleasant remedy. I gave it up.

Tincture of chloride of iron was a favorite remedy in erysipelas and scarlet fever, and many other infectious diseases, and seemed to be indicated in diphtheria. *Chlorate of potassa* was very justly held in high repute in the treatment of the different forms of stomatitis, besides having certain other clinical recommendations. I thought the combination of these two drugs ought to make an efficient remedy in diphtheria. For over ten years I have been using either the combination, or one or the other of the drugs, separately, in large and in small doses, frequently repeated and at long intervals. I have tried to ascertain whether any special effects followed their use in diphtheria. Certain patients have taken them for weeks without any apparent effect whatever on the progress of the disease. One young woman in St. Francis's Hospital, took ten grains of chlorate of potassa every two hours for eleven days, and still the disease progressed. We then gave her half-drachm doses of the muriated tincture of iron for ten days more, when she died. The membrane, which only occupied a portion of one tonsil when we began treatment, gradually extended over the pharynx, soft palate, through the nasal passages, larynx, and trachea, and was found at the autopsy lining the bronchi as far as the fifth or sixth division. Cases equally illustrative of the negative effects of these medicines have repeatedly come under my observation. Of course, it is not common for the disease to last as long as three weeks; at least the membrane, whatever the treatment; but such cases show that it *may* last three weeks, in spite of any power which these drugs possess. Many of the croup cases reported above had the full benefit of these remedies, but without marked result, so far as I could see. We know that quinine sometimes fails to cure intermittent fever; but, as a rule, it does not, and we prescribe it with confidence. But, with regard to drugs in diphtheria, I believe, as I have said before, that none of those now in use have any controlling influence over that disease. The only rational plan of treatment, in my opinion, is a symptomatic one. Stimulants and extra feeding are always indicated in grave cases.

The *surgical fever* following tracheotomy, ordinarily is slight, and does not demand quinine; but, if a malarial influence be present, it should be given in sufficiently large doses to destroy it at once. The tendency to *cardiac paralysis* can best be combated with digitalis, strong infusions of green tea given, if necessary, by the rectum, and champagne. I have tried strychnine, with negative results. *Diphtheritic nephritis* does not call for any special treatment, unless the urine become scanty, or uræmic symptoms be developed, or both. In case special treatment is indicated, large, hot, flaxseed-meal poultices, mixed with foxglove leaves, may be applied over the lumbar region, and sweet spirits of nitre given internally. Diaphoresis may also be promoted by the use of extra clothing and bottles of hot water rolled up in flannel, and placed around the patient. My experience with active diuretics in acute inflammatory diseases of the kidneys has led me to believe that they do positive harm. I have seen the quantity of urine voided steadily diminish with their use. When persistent vomiting depends on uræmic poisoning, small doses of morphine (given hypodermically if need be) seem to control it better than anything else that I have tried. In some cases there is complete suppression of urine, and the children then generally die in a few hours. The silly statement that this invasion of the kidney will not often occur if the disease be properly treated, is too absurd to require contradiction.

When once the membrane has seriously invaded the bronchial tubes, as evidenced by increased frequency of pulse, hurried breathing, rise of temperature, labored, "sawing" respiration, and harassing cough, a fatal termination is foreshown. Then steam, sprays, probangs, and bronchial emetics seem equally powerless to accomplish more than temporary mitigation of suffering. Finally, when all hope of recovery has been abandoned, small doses of morphine render the closing hours comparatively painless.

Prognosis.—My experience in tracheotomy for croup in this city, as well as my observation, would lead me now to believe that an average of not more than twenty or twenty-five per cent. of recoveries can be expected, if based on any considerable number of operations. The prognosis is always unfavorable; more so in some epidemics than in others; more so at some periods of the same epidemic than at others. During a lull in an epidemic, and also near its close, cases seem to be of a milder type and less protracted. In 1875 Jacobi said: "Since 1868 I have saved but a very small percentage of suffocating children, and still I cannot but stand by my former indication for the operation. It must not be omitted when obstruction in the larynx threatens to be the cause of death by suffocation." In 1868 he published a series of sixty-seven cases with thirteen recoveries—a good percentage when we know that he considers "no complication of disease or epidemic influence ought to be a contra-indication;" and, furthermore, that he is not likely to operate on a case unless the indication for it be clear.

My first ten cases were all fatal.* Dr. J. L. Little, of this city, had a nearly similar experience. Other surgeons with whom I have conversed on this subject have also had, at times, many successive failures. Success and failure do not alternate in regular order, from the very nature of the conditions. Gentlemen whom I have mentioned could probably make a very brilliant showing if they chose to select a small number of cures from some particular season or seasons. Again, some statistics are not reliable; not because the compilers had fraudulent intent, but from errors of judgment, and in diagnosis, and occasionally a treacherous memory has been at fault. Age is universally considered to have an important influence on results. Very young children—those under two years—rarely recover. Trousseau and others have attributed the increased mortality at this early age to traumatic fever. The cases herewith reported do not support that theory. My experience in the surgical diseases of children convinces me that children bear even the graver operations well; that tracheotomy produces little or no shock, and only slight, temporary, consecutive fever. If a temperature of 103°—105° should follow the operation—and this is giving the extreme limit—and continue for a day or two, it would not prove fatal. Infants, even, bear a much higher temperature for a more prolonged period, in other diseases, without serious danger. But at this tender age resistance to inflammatory diseases of the respiratory organs is comparatively slight. Tracheitis is always present after tracheotomy, and generally some little bronchitis.

---

* These cases are not reported in chronological order.

In consequence of this, plugs of partially dried muco-purulent matter and shreds of membrane are sucked into the delicate bronchi, the expulsive cough of the child is too feeble to drive them out, and little by little they are drawn farther in, until the obstructed bronchi are completely occluded and collapse of the air-cells supplied by them is the result. Again, the extra strength required to carry on respiration through narrowed air-passages cannot long be furnished by these little ones, so that a limited bronchial croup, which might not prove fatal in older children, will soon exhaust them.

The foregoing appear to me to be the two main reasons why tracheotomy is so unsuccessful in very young children. A more extended experience may change or modify my views ; but, so far, both a clinical observation of symptoms and the *post-mortem* examinations which I have made, support them. I have had no experience in tracheotomy for croup in young persons between seven years and adult age ; I have no doubt, however, but that the opinion generally held, that the chances of recovery steadily diminish after about the ninth year, is correct. The explanation therefor, is substantially the same as that given by Trousseau for the uniform failure of the operation in adults, viz.: "As the adult has the laryngeal orifice proportionally larger than the child, and the calibre of the trachea also proportionally greater, the air finds sufficient passage even when the walls of these conduits begin to be covered with false membrane; and, by the time that the symptoms of croup declare themselves, the diphtheria has had time seriously to compromise the ramifications of the bronchial tubes." In other words, laryngeal croup in the adult does not often prove sufficiently obstructive to demand tracheotomy ; asphyxia supervening only when the membrane has extended to the smaller bronchi, and this latter condition is not relieved by an operation. This is true in a modified way of older children and youth. It would be reprehensible, I think, in either case, to allow a patient to die of asphyxia without the chance afforded by an operation. No man can tell beforehand how far the membrane extends, and accompanying inflammation of the parts may dangerously close the glottis, if not the membrane alone.

I have seen three cases of croup in the adult. One has already been referred to in this paper. I assisted Dr. Leroy M. Yale in tracheotomizing a married woman thirty-five years old, for secondary croup complicating general diphtheria. The relief was not marked, and she died in about twelve hours ; no *post-mortem* examination was made. I attended a woman forty years old, for primary croup, the membrane first appearing on the vocal cords and secondarily on the pharynx and soft palate. This patient was seen by Drs. Louis Elsberg and Beverley Robinson. The constitutional symptoms were mild. No local treatment except steam and poultices was used. She recovered.

Is the so-called membranous croup more favorable for tracheotomy than diphtheritic croup ? Or, in other words, is that form of the disease in which the larynx is first invaded, or invaded coetaneously with the appearance of membrane on the tonsils, and accompanied by slight constitutional symptoms, more or less likely to terminate by recovery after tracheotomy, than a croup developed during the progress of an attack of severe diphtheria? It is impossible to answer this question by yes or no, except conditionally. It will generally be conceded, I presume, that diphtheria is a self-limited disease ; that, after running a course of from a few hours to several weeks, according to the character of the epidemic and the idiosyncrasy of the patient, it may end in the recovery of the person diseased, even without medicine. Now, the longer the disease has lasted before croup sets in, the shorter the time remaining before it (the diphtheria) will exhaust itself. Hence, a later-developed croup would be more favorable for operation than one setting in early in the disease, if the causes of death should be found to depend mainly on a prolonged duration of the constitutional affection after tracheotomy, and not on accidental complications. Again, if, as many believe, pseudo-membranous croup be simply laryngeal diphtheria, then the above argument would still hold good. If it be a disease *sui generis*, then clinical observation alone must decide the question. Now, I believe that a majority of the unavoidable deaths after tracheotomy for true croup are due to extension of the membrane into the bronchial tubes. It follows therefore, that, as a rule, unless the constitutional symptoms be very grave, a secondary croup coming on late in the disease is less dangerous than a primary one. In short, the longer the disease has lasted before croup sets in, the less likely the membrane is to travel beyond the larynx. Of the thirty-five cases herewith reported, eighteen appeared to be primary croup and seventeen secondary croup. Of the eighteen primary, two recovered ; of the seventeen secondary, six ! But this is too small a number on which to base a positive opinion ; besides, most of these cases of primary croup were not fair types of the so-called membranous croup as described by authors. Occurring sporadically they might be less unfavorable.

Delayed operations.—Cohen, of Philadelphia, in his excellent and comprehensive monograph, "Croup in its Relations to Tracheotomy," speaking of the ill-success attending the operation in that city, gives as a principal reason therefor that, "probably, as a rule, the operation is postponed too long." Still, he says, farther on : "The indication for the operation exists whenever it is apparent that death from suffocation cannot be averted by any other means." This is explicit, and perhaps as good a guide as any verbal rule that could be given. The only difficulty with rules is, that we do not all see through the same spectacles. Those with a limited experience are apt to exaggerate the urgency, while those who have seen more of the disease sometimes wait too long. Those who favor early operations will no doubt have the better results, because they will occasionally tracheotomize unnecessarily and will lose none by delay. No experience, however great, can predict with unerring certainty the changes which may take place in a few hours, and hence, croup patients should be seen often. Inflammatory œdema may set in and run a very rapid and fatal course. With my views as to the causes of death after tracheotomy, I cannot believe that the mortality is so much increased by delayed operations as is generally supposed. Now and then a child dies on the table that would not have so died had the operation been performed earlier. Possibly erysipelas and cardiac paralysis are somewhat more frequent when an extreme condition of asphyxia and exhaustion is allowed to take place before operating. But the more common causes of death will prevail, whether the operation be done early or late.

Time for operating.—The indications should be, as a rule : continuous labored respiration, with its accompanying recessions of the epigastric and suprasternal walls during inspiration ; commencing asphyxia, as shown by restlessness, pale or congested face, bluish lips and conjunctiva, and rapid, feeble, perhaps irregular pulse. Profound systemic poisoning, or other complication, may make it more judicious to operate earlier.

Contra-indications.—If a child be dying of croup, and the family, after hearing the case fairly stated, consent to the operation, and especially if they desire it, I believe it is right to make the attempt, no matter what the complications. I once operated on a young man, at his own and friends' request, who at the same time was suffering from waxy kidney, hip-joint disease, and general diphtheria. He lived twelve hours—long enough to whisper his thanks for the relief which had been given him.

Causes of death.—It is the general belief that pneumonia is a very frequent, if not the most frequent cause of death after tracheotomy for croup. This belief is based on: 1, the theory that cold air admitted directly to the lungs through the opened trachea has a tendency to excite pulmonary inflammation; 2, that the presence of the disease in the larynx and trachea has a tendency to produce parenchymatitis by continuity of tissue; 3, that certain physical signs, occurring some time during the first three days after the operation, are best explained by a diagnosis of pneumonia.

1. So far as I know, the cold-air theory has no foundation in fact. On the contrary, attempts to produce pneumonia in tracheotomized dogs by compelling them to inspire both very hot and very cold air alternately, did not succeed; because, as was claimed, by the time the prepared air reached the smaller ramifications of the bronchial tubes, it had, in accordance with well-known laws, become of the same temperature as *the reserve air of the lungs.*

Again, in the few cases in which I have seen the operation done in the adult for laryngeal stenosis, no pulmonary trouble whatever has followed. A young man was tracheotomized by me in St. Francis' Hospital for chronic laryngeal stenosis of several months' duration, depending on chronic laryngitis. At the time of the operation the symptoms were very urgent, and pulmonary percussion was very tympanitic. The relief was complete, and no pulmonary hyperæmia or bronchial catarrh resulted, although he was allowed to breathe the ordinary air of his ward. After wearing the tube several weeks it was taken out and the wound allowed to heal. Some weeks later stenosis had again become so great that death from asphyxia was imminent, and tracheotomy was again performed, with a like result. A similar case with a similar result was also under my care several years ago. Both of these patients were seen by Prof. Louis Elsberg. It is not an uncommon thing to see patients who have worn tubes for months, and even years, outdoors and indoors, and in all kinds of temperature, without detriment. But, in the case of these croup children, the air, as a general rule, is kept both warm and moist, and yet these *post-tracheotomy* symptoms are developed just the same.

2. Steiner quotes from Niemeyer (Ziemssen, vol. iv., pp. 250–1), in discussing the question of the causation of bronchial catarrh in croup, as follows: "When the thorax expands and the pulmonary alveoli enlarge without admitting a proportionate quantity of air, the air in the bronchi and alveoli must become rarefied, and must act upon the bronchial mucous membrane and inner wall of the alveoli in the same way as a cupping-glass does upon the skin, producing hyperæmia and increased transudation from the vessels in consequence of the diminished pressure upon the walls of the vessels." If it were true, as Steiner asserts, that "bronchial catarrh is an almost constant accompaniment of croupous laryngitis," we might discuss the question of its causation. But if we except those cases in which it precedes the croup, and those in which it depends either on uræmia or the actual presence of membrane in the affected bronchi, I do not think it is present, as a rule, to any extent. I base this opinion on quite a large number of cases carefully examined—examined, too, at a time when this condition should be found, if it be a consequential complication—just after tracheotomy was performed. There is laryngotracheitis in all post-tracheotomized cases, and generally a few bronchial râles may be heard on auscultation; but they are neither small nor numerous, nor have they a tendency to increase except from other causes than the simple extension of the original inflammation. I therefore discard this second theory.

3. The physical signs which, in fatal cases, gradually develop after the operation, are said to indicate pneumonia.

These are referable, for the most part, to the pulse, the temperature, and the respiration, and are generally first observed about the beginning of the second day after the operation, and continue to become more and more marked until the close of the third or the beginning of the fourth day after the operation, when death ensues.

The *pulse*, although it increases in frequency in these cases, has no uniform quality, being sometimes hard and wiry, at others soft and compressible. It indicates, in a general way, that the patient is not doing well, but it does not point to any particular lesion. The *temperature*, if carefully watched, will be found to differ from that of pneumonia in several respects. It does not generally run so high; it rises gradually and irregularly, and pursues no uniform course; it may even fall below normal at a period in the disease at which, if the cause were pneumonia, it should be at its highest point.

The *respirations* are hurried and labored, and accompanied by supra-sterno-clavicular and epigastric depressions during inspiration. The only points of resemblance between the respirations in these cases and those of pneumonia are, that in both instances they are hurried, and in both accompanied by cough and expectoration. In this connection I desire to correct the very common error into which writers on croup have fallen in stating that in the advanced stage of the disease the number of respirations is diminished. Even Riegel, in his article on "Bronchial Asthma," says: "I must recall the analogous and long-known reduction of the number of respirations in croup, laryngeal stenosis, and the like" (Ziemssen, vol. iv., p. 563). It is only necessary to count the respirations in any given case of croup to prove that the reverse of this statement is true. They *appear* to be infrequent because we see the whole of the painful process and hear the long-drawn *stridor.* In the condition now under consideration, however, the air, passing to and fro through the obstructed trachea and bronchi, produces a sound which, if heard at a little distance from the patient, closely resembles that made by slowly sawing a thin board with a small saw. Hence the graphic phrase, "sawing respiration," which has been applied to it. Unless due to some temporary and easily removable obstruction, as partial plugging of the tube with inspissated matters or a loose piece of membrane in the trachea, it is an almost certain precursor of a fatal issue. It is the most depressing sound to me that I have ever heard from a child suffering from croup. It is a sign of extensive bronchial croup. In addition to this difference between the respiration of pneumonia and that under consideration, there is usually the all-important symptom of obstruction to the entrance of air into the deeper recesses of the lungs—the supra-clavicular and epigastric recessions during inspiration. This is precisely what takes place when the larynx is obstructed, although not often to the same degree. In the former case, by opening the trachea and freely admitting air, these recessions no longer recur. But, unfortunately, in this secondary invasion no means of relief has yet been devised. Niemeyer, in discussing the mechanism of this symptom in primary croup, remarks: "If the air can enter the air-passages with freedom, the diaphragm, upon contracting, causes its *pars tendinea* to descend, but produces no incurvation of the ribs, for their resisting power is far greater than that encountered by the diaphragm in the elasticity of the lung or in the feeble pressure of the abdominal viscera. If, however, the tendinous centre be drawn up by the rarefaction of the air in the lungs, or if it be only fixed and hindered from moving downward, the inspiratory contractions of the muscles of the diaphragm must then, of necessity, cause the arch of the ribs to curve inward." But when the obstruction is very great, not only the epigastrium and tissues at the root of the neck sink in, but also the intercostal muscles. The column of air entering the lungs being smaller than normal, the bronchi are only partially filled, and to a certain extent collapse.

To compensate for this diminution of the size of the lung and thereby prevent a vacuum, the above changes in the relations of the diaphragm and chest-walls seem insufficient, and the deficiency is made up by a hyper-inflation by rarefied air of the easily distended air-cells. This abnormal dilatation of the air-vesicles I believe always exists in laryngeal or bronchial obstruction (if not complete), and is recognized by percussion during life. It was this vesicular dilatation during attacks of asthma, as recognized by percussion, that led Wintrich to believe that that disease could not depend on bronchial spasm; "for," he said, "the limits of the lungs should be rather rendered smaller by the asserted muscular spasm, as it is not to be supposed that it would always obstruct the exit of the air during expiration, and, on the contrary, would admit it into the vesicles during inspiration." The explanation above given of this condition in croup will apply with even greater force in asthma, because we have in the latter disease, in addition, a forcible reduction in size of the bronchi. It may be, however, that in bronchial croup *also* there is sometimes consequential bronchial asthma; there certainly is sufficient ground on which to base that theory. At all events, there is the strongest positive proof that we generally have associated with it more or less collapse of the lung, which makes an additional demand on the distensibility of the pulmonary alveoli.

The results of a *physical examination* of the chest in these cases do not point to pneumonia as the cause of the trouble. Percussion is usually more tympanitic than normal; but it may be very little changed, or there may be areas of dulness alternating with areas of normal or tympanitic percussion. This sign is not always a trustworthy one in young children, on account of rachitic deformity or congenital asymmetry of the chest-walls; so that, if the deviations from normal be not very marked, they will need confirmation.

The auscultatory signs likewise vary in different cases, and belong to one or more of these three diseases, viz., bronchitis, emphysema, and asthma. Sometimes no true respiratory murmur can be heard, nothing but conveyed sounds from the trachea and bronchi. Generally, when the case is far advanced, the râles are dry and muffled and the expiration prolonged. Over the dull areas there is often silence. Now, if any considerable portion of the lung were the seat of pneumonia, I think auscultation would reveal the bronchial breathing despite other morbid sounds.

Again, if this condition depended on pneumonia, would it so uniformly kill? And, if it did, would it always do it in about the same time—from 48 to 90 hours after the operation? My experience with pneumonia in children leads me to believe that a large majority recover from both the croupous and the catarrhal forms. Some of these croup-children, then, should, if pneumonia is what they die of. But, when "sawing respiration" is once established, death is inevitable. No exception to this rule has yet fallen under my notice either in my own cases or among those that I have seen under the care of other physicians. Finally, six *post-mortem* examinations on the bodies of children that have died in this condition—all that I have been able to see—confirm me in the opinion that bronchial croup, and not pneumonia, is the cause of death. Two of these autopsies are herewith reported and are specimens of all. Now, I do not wish to be understood as denying that a child occasionally dies of pneumonia after tracheotomy. I have myself given what I believe to have been an example. But what I do deny is that it is a common cause of death, or that it is the cause in a majority of those cases in which it is assigned as the cause. Steiner, in seventy-two autopsies, found lobular pneumonia only eight times and lobar diffuse pneumonia only six times. He does not state that in these cases, ever, it was the cause of death, although he does not state the contrary. I believe that a certain number of cases of collapse are called pneumonia, even at the autopsy, because no test of the permeability of the air-cells is made. As Juergensen says: "Inflation is the best means for distinguishing truly inflamed from simply collapsed portions." There can be no doubt but that many of these children *would* develop catarrhal pneumonia in the collapsed portions, if they could live long enough.

The sad, avoidable death of the little girl Kelly (No. XXXII.), from obstruction of the tube after all danger from the disease was apparently over, emphasizes the remarks of Cohen on this point: "It is therefore of the greatest importance that a competent attendant—by preference, a medical man of some judgment and familiar with the nature of the accidents which follow tracheotomy and the use of a tube—be at the side of the patient, or, at least, within immediate call, until all danger from this source has passed." Unfortunately, in a large number of cases this is impracticable. I have no doubt but that, with a competent nurse to take charge of the after-treatment, our percentage of recoveries might be considerably increased.

Diphtheritic nephritis is, I believe, more often a controlling cause of death than is generally supposed. Other causes of death found in the preceding tabulated statement need no special comment.

The following are some of the conclusions arrived at from the study of these and other cases of croup:

1. That the operation of tracheotomy on young children for croup, in its imminent peril to life, is one of the most dangerous operations in surgery.

2. That when the operation itself is safely completed, its secondary effects are not to be feared.

3. That from 20 to 30 per cent. of the cases operated on recover.

4. That tracheotomy will permanently relieve the distressing dyspnœa in more than half of the cases operated on.

5. That of those who subsequently die of bronchial croup, a considerable number suffer less than if they had been abandoned to their fate without an operation.

6. That it is always a justifiable procedure in croup, if the paramount factor in causing death be apnœa.

7. That the importance of operating early in the disease has been greatly exaggerated.

8. That early operations are sometimes needless operations.

9. That, as a rule, any prognosis based on the condition of the child before the operation is unreliable.

10. That nasal diphtheria, *per se*, does not add gravity to the prognosis.

11. That having a specially skilled nurse to attend the patients during the after-treatment would increase the number saved.

12. That, if there be an inflammatory exudative croup in contradistinction to diphtheritic croup, clinical observation has not enabled me to differentiate it.

13. That the medical treatment must be conducted on general principles, none of the pet drugs now in use being in any degree specific.

14. That the tube should be permanently removed as soon as respiration can be carried on through the larynx—the only certain test for this being to temporarily remove *both cannulæ*, and prevent the admission of air through the wound by stretching a piece of oiled silk or other impermeable substance over the opening.

15. That the tracheotomy wound, as a rule, needs no special treatment. If it be the seat of large and troublesome granulations, these may be destroyed with any of the stronger caustics—preferably nitric or acetic acid.

Doctor of Electricity (!).—The American Electropathic Institute recently applied to the courts in Philadelphia for a charter giving power to confer the Doctorate of Electricity. The charter was refused on the ground that the instruction was to be limited to the subject of electricity and its properties, while the public would be apt to look upon its graduates in the light of qualified practitioners of medicine and surgery; hence there was a source of danger to the community. The opinion of the Court contains the following well-based conclusions:

> Whatever may be the value of electricity and magnetism as curative agents, a knowledge of their principles in their application to disease does not comprehend the degree of learning which the law and the interests of society as well require in a practitioner of medicine.
>
> The corporation sought to be created would sustain, in its relation to the public, the character of a medical college, and it is this character, while its course of instruction is thus limited, that is without authority of law and liable to become a source of danger to the community.

FRACTURE OF THE INTERNAL CONDYLE OF THE HUMERUS WITH DISLOCATION OF THE HEAD OF THE RADIUS.

By THOMAS M. MARKOE, M.D.,

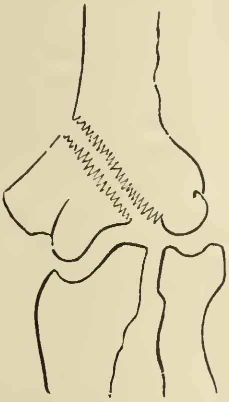
NEW YORK.

(Read before the New York Surgical Society.)

Fractures of the internal condyle of the humerus, embracing the whole or nearly the whole of the trochlea, are alluded to by all the systematic writers. The symptoms which characterize it are given by very few writers with any fulness of detail, and by none of them with any attempt at differential diagnosis; most of them being content with a bare statement of the injury, leaving the signs to be inferred, rather than attempting even an enumeration of them. Dr. Hamilton, however, in his latest edition, gives a very full account of the signs of this fracture, but does not dwell on diagnosis, and indeed, does not allude to the close similarity which the displacement sometimes presents to that of a dislocation of the forearm backward, though he quotes Sir Astley Cooper as saying that this injury is frequently mistaken for a dislocation. Gurlt also gives the signs of fracture of the internal condyle quite as fully and indeed rather more in detail than Dr. Hamilton, and both writers allude to the fact that the fracture of the condyle is sometimes connected with a dislocation of the head of the radius backward. Neither writer, however, gives any details as to the peculiar features of this last condition of the injury, except as quoting from a paper which I published in 1855 on this subject. At the time of preparing that paper my attention was chiefly occupied with the study of dislocation of the radius, and the article was intended to show the dependence of the dislocation upon the fracture; my confident belief being that a dislocation of the radius backward can never take place without one of three conditions being present, viz.: either, 1st, such a bending of the forearm on the arm that an angle of nearly 45° will show on the radial side of the joint; or, 2d, such a bend of the hand to the radial side as must be produced by drawing the whole radius at least an inch upward, while the position of the ulna remains unchanged; or, 3d, a fracture of either the shaft of the ulna or of the internal condyle. In following this idea the paper alluded to was published in the *New York Journal of Medicine*, in May, 1855, and it is upon the cases and descriptions of this paper that both Dr. Hamilton and Gurlt chiefly found such remarks as they offer on this subject. I know of no other author who has given special attention to this injury, and I therefore have considered that I might fairly claim to be the first to direct attention to its practical importance. On the more common form of fracture of the internal condyle it is not my purpose to dwell. All the writers who specially mention it agree in saying that it is accompanied with but little displacement, and that in a backward direction, increased during extension and diminished during flexion of the forearm on the arm. At the same time crepitus is mentioned, and local mobility of the separated fragment when firmly grasped. These injuries are stated to be always produced by direct violence, as by a fall on the elbow, and very little is said about the ultimate effects on the motions of the joint.

I have no fault to find with this account of the injury, and nothing to add to it. I consider that it gives a fair picture of the accident in a certain number, perhaps a majority, of its examples. I have long been convinced, however, that there are a certain number of these cases which have a different cause, take a different course, present some very different features, and tend, if not recognized, to a much more serious impairment of the usefulness of the elbow-joint than the statements in the books would lead us to anticipate.

In these exceptional cases the original lesion is the same as that described as belonging to fracture of the internal condyle, viz., a breaking off of the condyle in such a way as to include a considerable portion of the trochlea in the broken fragment. If now the injury has been received in such a way that the force has been applied directly to the elbow, there is no mechanical reason why any marked displacement should occur. If, however, the force has been received on the hand and transmitted through the ulna to the internal condyle, then it seems manifest that if the force be great, and if it be continued in action after the bone has given way, the tendency to displacement will be in the line of the acting force, and the whole forearm will tend to be thrown backward, precisely as happens in an ordinary dislocation. This is the condition of the injury to which I wish to ask the attention of the society.



And here it seems to me that a more just appreciation of the points involved will be gained if we consider a moment the physiology of the elbow-joint. A glance at the diagram will remind the Society that, of the two bones of the forearm, the ulna is the one which is really articulated with the humerus. The radius, though touching the capitellum, to which it is loosely attached, being chiefly articulated with the ulna, to which it is bound by three sets of ligaments, is so arranged as to allow the radius to roll around the ulna in the movements of pronation and supination, at the same time that it is so firmly attached to it that any separation of the two bones can only be accomplished by extraordinary violence, and is in point of fact one of the curiosities of surgery. Physiologically speaking, the radius may be regarded as an elongated carpal bone, its shape and attachments being such as to give it the movements of pronation and supination, which are truly movements of the hand, and not of the forearm. It is also evident that the connection of the radius with the humerus is not a physiological necessity. While we must acknowledge that the movements of flexion and extension of the forearm on the arm are steadied and strengthened by the increase of the base line at the point of motion, it is at the same time evident that all the movements of the forearm and hand can be supposed to be executed by a radius which does not reach the capitellum. This comparative independence of the radius in its relation to the humerus has, in the study in which we are engaged, this practical significance: it shows how force transmitted through the forearm is received principally on the trochlea, and it also shows that, if the trochlear support is in any way lost, the radius can do but little to prevent complete displacement of the joint-surfaces, and this chiefly by reason of the looseness and weakness of its attachments to the capitellum. These remarks I thought it desirable to make, that we may more intelligently appreciate some of the points in the history of the fracture which I wish to describe. The following case will serve to bring the subject definitely before us. I copy from my case-book the notes as taken at the time, now more than twenty years ago.

"Michael Lee, æt. 10, was admitted to the New York Hospital, Oct. 11, 1859. Five days before he had fallen from a horse, striking on his left side, with his arm twisted behind him. Great swelling and ecchymosis took place immediately, and at the time of his admission had not subsided sufficiently to justify us in making a thorough examination of the injury. The arm was laid in a comfortable position, and evaporating lotions applied. On the 17th the swelling had so far subsided as to give us a chance to examine the fracture. The internal condyle and the olecranon were in proper relation to one another, while the head of the radius had left the external condyle, and was easily felt rotating behind and to the outside of it. The whole aspect of the elbow was that of dislocation backward, the end of the olecranon projecting about an inch backward, and the end of the humerus making a rounded projection on the anterior face of the joint. The parts were so easily movable that it could further be distinctly made out that a considerable fragment of the internal condyle, broken from the shaft of the bone, remained attached to the olecranon and moved with it. The whole displacement could be easily reduced and the deformity removed, while on letting go the limb it was immediately reproduced. Dr. Van Buren saw the case with me and recognized the facts as above stated, and without hesitation agreed with me in the diagnosis of fracture of the internal condyle, involving so much of the basis of support of the olecranon as to allow of its displacement backward to a sufficient extent to permit the head of the radius to be also pushed backward, as in ordinary luxation. The displacement was reduced, and the arm placed at an angle less than a right angle, and so retained by an angular tin splint, a firm pad being placed on the prominent end of the humerus to keep it in place. On the 30th the apparatus was removed without my knowledge, and the young man reported that union of the detached fragment was firm and the joint in good shape. He was discharged the next day, Dec. 1, 1859, without my having had an opportunity of examining the arm."

It will be noted that the leading features here presented are: 1st, a close resemblance to an ordinary dislocation of the forearm backward; 2d, while the head of the radius has left its usual relation to the external condyle and can be felt below and behind it, that the olecranon, though thrown behind its natural position, has not left the internal condyle, but remains in its normal relation to it. The internal condyle can be felt to have followed the backward movement of the olecranon, and a sharp projection about an inch above the joint shows where the condyloid ridge of the humerus has been interrupted by the fracture; 3d, seizing the fragment thus displaced and moving it backward and forward, it can be felt to move independent of the external condyle, and in this manipulation crepitus is easily produced; 4th, on the anterior aspect of the joint a somewhat sharp protuberance can be felt, which is the end of the humerus from which the internal condyle has been detached. These are the signs which are derived from manual examination of the bony prominences of the joint. If clearly made out they are sufficient to establish the nature of the injury. Another sign, however, is not less important, and that is the facility with which the displacement is reduced. This easy reduction and easy displacement arises from the fact that the reduction is merely the replacement of the head of the radius in its normal position, with the restoration of the fractured surfaces to their proper apposition one with another, and from the further fact that when thus replaced there is nothing to hold the fragments together, except the head of the radius with its shallow cup in contact with the capitellum, which it does not embrace, and whose ligaments are already torn through by the injury. The slightest movement is sufficient to displace this head of the radius from its unstable position on the capitellum, and, when thus displaced, there is no longer anything to restrain the fractured internal condyle from backward displacement, and the original deformity is thus easily reproduced.

The diagnosis lies chiefly between the injury in question and the dislocation backward of the forearm. The resemblance between these two injuries is so striking, particularly after swelling has taken place and has somewhat obscured the anatomical points, that a mistake is easily made—a mistake, as I shall show hereafter, fraught with very serious danger to the ultimate usefulness of the joint. The diagnosis is founded upon three points: 1st, the changed relations of the bony prominences around the joint; 2d, facility of reduction and marked tendency to reproduction of displacement when unsupported; 3d, sharpness and smallness of anterior prominence of the lower end of humerus.

With regard to the first, we must note that the whole humeral extremity in the dislocation retains its relation to the internal condyle, and this latter can be felt forming the termination of the condyloid ridge, and placed far in front of its proper relation to the olecranon, which is projecting strongly backward and upward. In the fracture, on the other hand, the condyloid ridge is felt to be interrupted an inch or more above the joint, and the olecranon has not quitted its normal attachment to the internal condyle, which has followed it in its backward displacement. The change in the position of the head of the radius is the same in both injuries, and therefore, taken alone, will not assist us in their discrimination.

2d. Facility of reduction and redisplacement. In dislocation the prominent edges of the articular cavities, the untorn portions of the uniting ligaments, and muscular tension all combine to oppose obstacles to the return of the dislocated bone; but, when once the bone is back again in its proper place, some considerable force and some considerable extent of movement is required to reproduce the deformity. When once a dislocated elbow is reduced, we feel sure that by properly supporting the limb, and not allowing any moving of the elbow-joint, we shall retain all that we have gained, and we should feel confident, with these precautions, if we did not see the limb again for many days, that it would be found in perfect position. In the fracture, on the contrary, the easy reduction is followed by easy displacement, so that, as has happened in several of the cases I have seen in consultation, the surgeon has been astonished, after a perfectly satisfactory reduction of the supposed dislocation, to find on his next visit the original deformity exactly reproduced. This feature is not only strikingly characteristic of the injury in question, but is itself the explanation of the importance which should attach to the accurate recognition of its nature.[*]

This brings us to the prognosis. It may be very briefly stated: it is good if the injury be accurately recognized; it is very bad if it be misunderstood. A moment's reflection on the mechanical principles of an ordinary hinge will suggest the dangers which are likely to follow a fracture through the articular surfaces of the elbow-joint; the best example is the skeleton of a true ginglymoid articulation. If any portion of the receiving or received parts of an ordinary hinge be bent out of line, the movement of the hinge is impaired or destroyed. If the bent portion be restored to line, the movements of the hinge are again perfect. In the complex hinge of the elbow-joint any deviation of the articular surfaces from the line of motion of the joint, if once consolidated, will impair that motion, or make it impossible. Of course a total destruction of the motions of the joint from this cause can hardly be supposed to be possible; but such a degree of impairment as permanently to restrain and diminish the ability to flex and extend the forearm has actually occurred in several of the cases I have seen. On the other hand, if the nature of the injury be clearly made out, and the surgeon be careful and watchful, as well as skilful in applying his dressings, we may with confidence promise a perfect restoration of all the functions of the joint. This, in my mind, is what makes this fracture one of so great a practical interest, viz.: that it is extremely liable to be misunderstood; that, if so misunderstood, it entails permanent damage upon the joint, and, what gives crowning interest to the study, we may by intelligent management entirely neutralize the threatened dangers.

The treatment is directly deducible from what has been said of the nature of the injury. It consists, first, of reduction, and second, of retention. The first indication is usually very easy of accomplishment. It is the second that demands the surgeon's vigilant attention. The constant tendency of the forearm to slip backward is, I have thought, best counteracted by bending the elbow at least to a right angle after the reduction has been completely accomplished, and then binding the limb to a grooved tin splint, which accurately fits the dorsal surface of the arm and forearm down to the wrist. This alone would doubtless be sufficient to steady the fragments in many cases; but when, as is occasionally the case, the tendency to displacement is very great, a slightly concave splint on the anterior surface of the arm, extending from the shoulder nearly to the elbow, acts directly to keep the upper or humeral end from pushing forward, and very much improves the retentive power of the entire apparatus.

Reasoning theoretically, I have thought that the joint line could be most securely preserved by bending the forearm to something less than a right angle with the arm. This idea occurred to me on noticing how the head of the radius mounts on the capitellum in the flexion of the forearm, until in extreme flexion it almost touches the anterior surface of the humerus above the articulation. On glancing at the skeleton it will be seen that the head of the radius, thus rising upon the capitellum, prevents backward displacement more and more perfectly, as it rises, until it reaches an angle, say of 80°, with the humerus, where I have thought its supporting power was greater than at any point of either greater or less flexion. If this be true, then, to secure all the advantages of position, we should aim to keep the elbow bent to about this angle, and this theoretical idea has been confirmed by quite a number of trials I have made in the few cases I have had an opportunity of treating. The important point in the treatment may be stated to be constant, watchful care that the original deformity be not reproduced. This secured, the future of the joint is assured.

---

[*] The third diagnostic point needs not to be dwelt upon. The ulnar half of the articular extremity being gone, the remaining radial half makes an anterior prominence, which is smaller and sharper than in the dislocation, and the prominence is situated on the radial side of the joint, a manifest vacuity being felt, where in the dislocation we should have the prominence of the trochlea making its part of the forward protrusion of the humeral extremity.

As in all cases where fracture involves joints, early passive motion should be employed. In the third week, I think, slight movements of the joint, made by the surgeon himself, with all due care to prevent any yielding of the fragment which has not yet been solidly united to the shaft, and repeated every day, will prevent, as far as it is preventable, the stiffness which always follows this accident, and these passive movements should be supplemented in the fourth week by some voluntary exercise carefully increased as it is better and better borne.

In conclusion, I think I may state that, even when much bony deformity has resulted, and as a consequence much restriction of the movements of the joint, something can still be accomplished, if the union be not too solid, by persevering and courageous efforts, both on the part of the surgeon and of the patient, to overcome the resistance by the steady application of force. This, in slight cases, may be accomplished by the surgeon forcing the movements beyond the point of arrest, by steady and firm pressure with his unaided hand. If this be done daily, and particularly if these efforts are cordially seconded by the patient's own voluntary exertions, much can be accomplished. The patients are almost always young; indeed, I have never seen a case over twenty, and as the obstruction arises not from rigidity of muscle or ligament, but from inequality of hinge-surface, in these young bones considerable deformity, in the early weeks after the healing, can be overcome by patient perseverance. In one rather bad case I had Mr. Tiemann make me an instrument by which forced flexion and extension could be made and maintained, and in this instance, although on his recovery from the fracture much impairment of motion existed, I finally succeeded in gaining perfectly every movement of the limb.

The number of cases in which the peculiar conditions noted above prevail, will not be large in any one man's experience; but it seems to me that one elbow-joint, crippled by the nature of its injury being misunderstood, would make any conscientious surgeon feel that want of knowledge of the simple facts I have rehearsed would not exonerate him either *in foro conscientiæ*, or before the tribunals of this wicked world, where a suit might be brought for *malapraxis*.

* * *

Opium Smoking.—A Prize of $250 has been offered by an English gentleman, interested in the matter, for the best essay on the medical means of counteracting the effects of opium-smoking in China. This essay should contain suggestions as to the best method of conducting an opium refuge (or hospital) in that country. Dr. Risdon Bennett, Dr. Sieveking and Sir Joseph Fayrer will act as adjudicators. If thought advisable, a second prize of $125 will be given.

A CASE OF EPITHELIOMA OF THE RECTUM,

In which the Operation of Proctectomy was Performed.

Reported by ALFRED C. POST, M.D., LL.D.,

NEW YORK.

Joseph Mowett, æt. 53; Scotland; widower; machinist. Admitted into Presbyterian Hospital, April 1, 1880. Family history good. Enjoyed good health until last summer, when he had an attack of yellow fever. Eight weeks before admission he began to lose flesh and strength. Three weeks later he began to have frequent fluid passages from his bowels, with severe bearing-down pain, which continued to the date of his admission, with slight intermissions. The loose evacuations contained mucus and blood. At the time of his admission he had seven to ten passages in twenty-four hours. Examination with a finger revealed an irregular, indurated, cock's-comb shaped tumor an inch above the anus, at the junction of the left and posterior wall of the rectum, about two inches in length, and involving two-thirds of the circumference of the bowel. Chalk mixture with camphorated tincture of opium was ordered to relieve the diarrhœa.

April 5th.—Passages more nearly normal in appearance, less frequent, and less painful.

April 10th.—Continued improvement; three to five passages in twenty-four hours, very little pain, no mucus, but occasionally a little blood. A consultation of the surgeons was held, and the operation of proctectomy was advised.

April 12th.—The patient was etherized, and the operation performed in the following manner: Two semi-elliptical incisions were made, one on each side of the anus, an inch from its margin, meeting in the perineum in front, and near the coccyx behind. These incisions were carried down to the muscular coat of the rectum above the sphincter, the rectum being drawn down by a vulsellum. The fibres of the levator ani were divided, and the incision was extended upward, until a line was reached corresponding with the upper extremity of the neoplasm, as felt by the introduction of a finger within the gut. The morbid growth occupied the left side of the rectum, from near the median line posteriorly to the junction of the left with the anterior wall of the intestine. An incision was made through the rectum, a third of an inch on the right side of the median line posteriorly, and another through the anterior wall of the bowel near the median line, leaving between the two incisions a strip of healthy tissue, including about two-fifths of the circumference of the gut. The left side, including the diseased growth, was then drawn down and divided transversely above the diseased portion, little by little, each bleeding vessel being tied in the progress of the operation, until the whole mass was removed. The portion of the sphincter connected with the sound flap on the right side being regarded as superfluous and interfering with drainage, was removed, and the remainder of the flap secured by suture to the skin. Toward the close of the operation the circulation became quite feeble, and the pulse at the wrist imperceptible. Two hypodermic injections were administered, each containing thirty minims of whiskey.

6 p. m.—The patient has recovered from the effects of the ether, but he has a haggard look and a feeble

pulse. Half an ounce of whiskey was given to him, and the dose was repeated after an hour.

10 P. M.—Circulation much improved. Patient does not complain of any pain.

April 13th, 2 A. M.—No urine has been passed since the operation. A catheter was introduced, and seven ounces were drawn off. As there was some oozing of blood from the wound, a mixture was prepared, containing forty minims of liquor ferri subsulphat with an ounce of water, and the patient was directed to take a drachm every three hours. In the middle of the day, as the quantity of urine drawn off by the catheter was scanty, infusion of digitalis was ordered, half an ounce three times a day. In the afternoon he had a movement of the bowels without pain. The stool was clay-colored and cylindrical. The wound was dressed with lint, moistened with carbolic oil, 1 to 10. The patient was directed to confine himself to a liquid diet.

April 15th.—Patient continues to do well. He takes his food regularly. He has two or three semi-solid stools in 24 hours. The wound is repacked with lint, moistened with carbolic oil after each stool.

April 17th.—Urine is regularly drawn off with a catheter. The secretion is more free, and the infus. digitalis was directed to-day to be discontinued. The wound is granulating, and is in a healthy condition.

April 20th.—In passing the catheter, some difficulty is experienced, there being an apparent obstruction in the membranous portion of the urethra. A steel sound of 30 mm. was passed into the bladder, stretching, and probably divulsing the urethra.

April 21st.—Since the passage of the sound, the patient urinates without a catheter. He has occasional cramps in his bowels, which are always relieved by sulph. morphia, gr. $\frac{1}{5}$.

May 15th.—There has been steady improvement in the condition of the patient. The right side of the rectum, which was attached by sutures to the integument, united with the skin by the first intention. The left side, which was widely separated from the skin, has come down within half an inch from it, and the intervening space is filled with healthy granulations. There have been occasional attacks of diarrhœa, always relieved by bismuth, in five-grain doses, combined with sulph. morphia, gr. $\frac{1}{6}$. The patient's mind is a little confused. He has a singular hallucination, that the members of the house staff have conspired to chloroform him and cut him up. This hallucination probably originated in the fact that there was a case of secondary hemorrhage in the same ward, in which the house-surgeon was obliged to reopen a wound to secure some bleeding vessels.

June 3d.—The patient has for some time past been able to put on his clothes, and to walk about the ward and the corridors. He continues to be troubled with his old hallucination, and to-day he absconded from the hospital.

In reviewing this case, its most remarkable feature seems to be the very moderate amount of local distress, or of constitutional disturbance, following so grave an operation.

On the 13th of April, the day after the operation, the highest rate of the pulse was 96, and the highest temperature 100°. On the 14th, pulse 98; temperature 101°. On the 15th, pulse 100; temperature, 101°. On the 16th, pulse 96; temperature, 101.2°. On the 17th, pulse 96; temperature, 101°. On the 18th, pulse 92; temperature, 100.7°. On the 19th, pulse 92; temperature, 100.6°. On the evening of the 20th, the temperature descended to 98.5°, and from that time pulse and temperature were normal. The local symptoms, from the day after the operation, were equally mild. There was scarcely any complaint of pain, and the healing process went on without interruption. The progress of the case in all respects, except the mental condition of the patient, was entirely satisfactory.

It is a matter of regret that the patient could not be induced to remain longer in the hospital, and that the opportunity of watching the result of the operation for a more extended period was lost. The patient was under observation for a little more than seven weeks after the operation, and during this time the very extensive wound had nearly healed, and there was reason to hope that he might enjoy a long reprieve, if not a full immunity from a return of the disease.

Reports of Hospitals.

BELLEVUE HOSPITAL.

Notes of Practice and Peculiarities in Treatment.

LARYNGEAL SPASM—GENERAL CONVULSIONS—RACHITIS—SUDDEN AND THREATENING ASPHYXIA—CATHETERIZATION OF THE LARYNX—RECOVERY.

THE following case was interesting with reference to several points. A baby, a few weeks old, had the appearance of being in a healthy, well-nourished condition. It, however, had persistent general convulsions and attacks of laryngeal spasm. On making a careful examination the evidence of rachitis was found in the beaded condition of the ribs and soft spots in the cranial bones. It was believed that the general convulsions and the spasms of the larynx depended upon the general conditions included in the term rachitis. On examining the pharynx a laryngeal spasm was promptly produced, and the baby suddenly became asphyxiated to an alarming extent. Respiration ceased at once, and the face was livid. Artificial respiration was resorted to at once, but neither Schutze's nor Marshall Hall's, nor Sylvester's method did the least toward restoring the child. The tissues of the larynx were completely relaxed; but there was not sufficient life in the child to enable it to breathe. The heart continued to beat. A male silver catheter was quickly introduced through the larynx, and respiration was immediately restored. The general convulsions were subsequently controlled by the use of chloroform. At the end of a week the laryngeal spasm had not returned, nor had the general convulsions; and the child seemed to be better for having passed through the dangerous ordeal. The practical point was the catheterization of the larynx in preference to tracheotomy in a case demanding extremely prompt action, in order to prevent death from sudden asphyxia.

PHLEGMASIA ALBA DOLENS.

The following cases exhibited features worthy of note: A woman, æt. 42, was confined Feb. 3d. The labor was tedious, the breech presented, and the child was not saved. She then had a fever that lasted for some time, accompanied by sweating and exhaustion, and finally she was brought to the hospital.

Seven weeks after parturition, *an exceptionally late period*, phlegmasia alba dolens developed. The treatment adopted was leeching and poultices for the pain and tenderness, and it was believed that probably they had some effect in shortening the duration of the active stage. The limb was kept at rest. After the acute symptoms had subsided, agents to promote absorption were indicated, and that upon which chief reliance was placed was the flannel roller bandage for the toes, upward to the upper portion of the thigh. The patient should be encouraged to move about some, as motion stimulates the circulation and thus favors absorption. So long as any hardness remains in the course of the veins *friction should be avoided;* for, in a sufficient number of cases to give warning, a portion of the thrombus has been detached, and, entering the circulation, has done irreparable damage. A second case of phlegmasia alba dolens was seen, which was exceptional in that it was double, and was interesting in comparison with the other case in that it began on the eighth day after a tedious labor.

SECONDARY HÆMORRHAGE AFTER TEDIOUS LABOR.

A woman was confined on March 28th. Labor was tedious, but uncomplicated. Five days after parturition, and while making a good recovery apparently, she was moved from the Maternity Hospital because of the appearance of puerperal fever in the wards. At twelve o'clock on the night following the day on which she was removed, she began to bleed from the vagina; the discharge continued until six o'clock in the morning, and, although profuse, did not cause any serious constitutional disturbance. On searching for the cause of the hemorrhage, it was learned that the placenta was said to have been partially adherent, and the suspicion arose that a portion of it still remained, although it was supposed, at the time of labor, that it was completely removed. The suspicion was confirmed by passing the curette carefully over the internal surface of the uterus, and removing one or two small pieces of placenta that had been retained. The operation was followed by ergot and the hemorrhage was at once arrested, and had not returned. There was no laceration to account for the hemorrhage. Objection was made to the use of the tampon in such cases, even five days after labor.

PNEUMONIA—VALVULAR DISEASE OF THE HEART—SUDDEN DEATH.

The following is a complete history of a case that terminated fatally 14 hours after admission to the hospital: A middle-aged man was taken sick five days previously. Vomiting was the first symptom, and the material vomited had a yellowish color. In the afternoon of the same day he began to throw up blood with coughing, and he thought that he raised about a pint, which was of a bright red color. Afterward, the vomiting returned, independent of the cough, and he threw up dark colored blood. He did *not* have a chill. He had, besides the vomiting and raising of blood, pain in the left side below the ribs, pain at the pit of the stomach, and over the latter region there was a good deal of tenderness on pressure. When admitted to the hospital, his cough was harassing and was attended by expectoration, viscid and colored, but prune-juice rather than brick-dust. He coughed and vomited and raised blood more or less during three days, including that on which the attack began. He had had articular rheumatism. He had been in the habit of going on sprees, but had not drank alcoholics steadily and regularly. His arm was amputated at the shoulder in 1873. His family history was unimportant.

Physical examination.—Cheeks flushed, and of a dusky color. Abdominal respiration: Pulse, 110, regular, and of fair strength; temperature, 102⅓° F., in the mouth; respiration, 40, and somewhat panting. Tongue moist; countenance not notably anxious. The apex of the heart was beating in its normal position; no evidence of cardiac hypertrophy; no sinking under the clavicles upon taking a full inspiration.

On *percussion* in the infraclavicular region, resonance was found to be more marked upon the left than upon the right side. On *auscultation*, vesicular respiration was heard on both sides. A murmur was heard with the first sound of the heart, having its greatest intensity at the junction of the second rib with the sternum on the right side, and was not conveyed toward the apex.

Posteriorly, vocal fremitus was more marked upon the left than upon the right side in the infrascapular region. On *percussion*, there was dulness, almost flatness over two-thirds of the left side of the chest, and a great deal of tenderness. On *auscultation*, expiration was more marked than inspiration over the left lung, tubular breathing from the top to the bottom of the pleural cavity, at the end of the inspiratory act a distinct friction sound was obtained, but no râles in any locality. Over the right lung was exaggerated respiration. The diagnosis was pneumonia, and the points specially interesting were, first the vomiting, which seemed to take the place of a chill at the onset of the disease, and second the hemorrhage, which, when it ushers in an attack, indicates that a large amount of lung will be involved, usually the whole lung, and also that the patient's general condition is bad at the time of the occurrence. Such cases do not resolve well, it was remarked; and gangrene of the lung is very liable to occur under such circumstances. The cardiac complication was unfavorable, but an aortic was regarded as more favorable than a mitral lesion under such circumstances. From an examination of the patient's toes and fingers it was evident that he had a gouty diathesis, but if, so far as the urine could indicate, the kidneys were in good condition, the prognosis was tolerably fair. The urine had not been examined, as the patient had just been admitted. The treatment was chiefly to allay the harassing cough which was wearing out the strength of the patient, and, accordingly, a hypodermic of Magendie's solution of morphia, ♏viij., was given. The patient was to be kept well covered in bed and put upon a nourishing diet, consisting of all the milk he could drink, all the cold water he wished. In the evening of the same day he was feeling quite comfortable, and had rested some under the influence of the morphine. At about 3 o'clock on the following morning he died.

At autopsy, made twelve hours after death, consolidation of nearly the whole of the left lung was found, together with a moderate amount of pleuritic exudations. Red hepatization just began to pass into gray, as shown by microscopical examination. Right lung normal. Heart-thickening and retraction of the aortic valves and stenosis, so that the orifice barely admitted two fingers. Moderate hypertrophy of the left ventricle. Mitral valve thickened and orifice narrowed so as to admit scarcely more than one finger. The tricuspid valve was also thickened, and the orifice would not admit three fingers. There were no vegetations, and the muscular tissue presented a healthy appearance.

ANEURISM OF THE AORTA AND THE INNOMINATE—OPERATION SUGGESTED.

A middle-aged woman had been sick seven months; has had a fluttering about the heart, and pain in the precordial region, especially after excitement of any kind. She had also occasionally had a peculiar sensation of weakness come over her, referable to the cardiac region, and so marked as to oblige her to sit down at once when it appeared, and those spells were as apt to come on without as with physical exertion and excitement. Two days previously she noticed, for the first time, that her voice was changed, and also discovered a lump in her neck. On physical examination, a marked pulsation in the neck was noticed over the entire region between the scaleni muscles and above the sternum. On palpation, a distinct tumor was felt that had a dilating impulse, and extended about an inch above the sternum on a line with the junction of the clavicle with the sternum. When the fingers were passed behind the sterno-clavicular articulation, the pulsation could be felt very distinctly. On percussion, dulness was found to extend downward into the chest cavity below the sternum about three inches, upward into the neck and over toward the right side of the trachea. The right radial pulse was feebler than the left. On auscultation, a double murmur was heard over the heart, and it increased in intensity until the base of the organ was reached, when it was heard with its maximum intensity, although nearly as loud above the sternum. There was some cardiac hypertrophy. The diagnosis of aneurism of the innominate artery and of the aorta was made, and ligation of the carotid and subclavian arteries suggested.

HYDROCELE OF THE SCROTUM.

A patient, a man somewhat advanced in years, was seen, who had had his hydrocele treated with an injection of absolute alcohol. Dr. Gouley removed fourteen ounces of fluid with the aspirator. The same quantity was removed at his second visit, and then three drachms of absolute alcohol were thrown in before the needle was withdrawn. The result was a cure, as shown by an examination made nearly two months after the operation.

The multiple puncture was practised on a congenital hydrocele, and the case was progressing favorably.

EXTERNAL URETHROTOMY—RECONTRACTION—CONTINUOUS DILATATION.

The case was interesting in the following particulars: External urethrotomy had been performed successfully *eight* years previously. Recontraction had occurred to such an extent that he came for treatment within the last month. Continuous dilatation, instead of cutting, was practised, and the stricture had been dilated from two to fourteen inches in three weeks.

ACUTE BRIGHT'S DISEASE.

The following cases were noted, because of certain peculiarities which they presented:

Case I.—Mr. ——, æt. 46; a printer; native of United States; was admitted to the hospital on the 8th. Family history unimportant. He had been accustomed to drinking strong drinks moderately. His health was good up to *three* years ago, when he had chills and fever, and, at that time, was told that he had kidney disease. He recovered, and no symptoms of renal disease manifested themselves until about four weeks previous to his admission. The question arose, did he fully recover, or did he have a latent kidney affection during all the time he believed himself to be in perfect health? Probably the latter. One month before admission he began to suffer from pain in his back, and his feet and legs began to swell; his abdomen was slightly enlarged, he had headache, and passed a smaller quantity of urine than usual. On admission, he had some œdema of the lower extremities, the quantity of urine discharged was less than normal, somewhat smoky, had a specific gravity of 1010, and contained albumen and small hyaline casts. Two weeks after admission, the date in which this note was made, his urine was still somewhat smoky. The indication was to increase the quantity of urine discharged without irritating the kidneys. The acute symptoms had passed away. He was put on the free use of milk, and half an ounce of the infusion of digitalis with twelve grains of acetate of potash were given every three hours. On the day following his admission, he passed ℥ xvi.; on the second day, ℥ xxxiv., and the œdema had almost entirely disappeared. On the 23d the urine had an acid reaction, specific gravity 1012, and contained albumen; but the œdema had disappeared, the patient's appetite was good, and his general condition was so fair that he regarded himself as about as well as ever.

Case II.—A man, æt. 73, native of Ireland, and a laborer, was admitted to the hospital on the 20th. His family history was unimportant. He had used liquor and beer moderately. He had enjoyed good health up to *nine* years ago. At that time his feet and legs were swollen, his abdomen increased in size, he had shortness of breath, passed a small quantity of urine during his sickness, which lasted a month, but he was not confined to his bed during the whole period. He made an apparently complete recovery. From the history, it was concluded that the man had acute desquamative nephritis *nine* years ago. If so, it was exceptional; because at that age he had no right by rule to have the affection. About three weeks before admission he began to pass bloody urine, and his feet and legs began to enlarge. In this case there was suspicion that nine years ago the patient was left with the chronic form of the disease. When admitted, his lower limbs were œdmatous, also his scrotum and penis, there was slight œdema of the face, and a small quantity of urine in the abdominal cavity. He had some dyspnœa and cough. His bowels were loose and his appetite was good. His urine was smoky, had a specific gravity of 1014, and contained albumen and small hyaline casts.

The treatment was conducted upon the same principle as in the first case, but different remedies were used.

℞. Potass bicarb............... grs. xxx.
Infus scoparii............... ℥ ss.
S. To be given every three hours.

On the second day after admission the œdema was less, cough less, and his general condition was notably improved. On the following day his urine was yet slightly smoky, had a specific gravity of 1011, was alkaline, and contained albumen. His general condition was improving, and the treatment was continued. Milk was an important factor in his diet.

In Case III. phenomena similar to those given were observed, and the patient was taking acetate of potash, with marked benefit. The urine had increased in quantity, and the patient's general condition had improved.

In Case IV. the indication for treatment was substantially as in the foregoing cases, and the infusion of triticium repens (dog-grass) with bicarbonate of potash was used with very satisfactory results.

RECTAL ALIMENTATION.

In a case of severe and persistent vomiting, with pain, dependent on subacute gastritis, the patient, a male, æt. 34, was received. Day and night nutritive enemata were administered every three hours, composed of the following articles:

Milk, ℥ ij.; half an egg; whiskey, ℥ ij., and McMunn's Elixir of Opium, gtt. x. The vomiting and pain were at once relieved. Two days previous to taking this note defibrinated blood was substituted for the above mixture, and ℥ iij., every three hours, were employed with satisfactory results.

ARTICULAR RHEUMATISM, VALVULAR LESION OF THE HEART—EXCEPTION WITH REFERENCE TO BOTH.

A male patient, æt. 47 years, and a laborer, was admitted on the 13th. Family history unimportant. He had been accustomed to the use of both liquor and beer, yet said he never drank to excess. He had always had good health until two years ago, when he had his *first* attack of articular rheumatism. The case was exceptional in that the first attack of rheumatism occurred when the patient was forty-five years old. If rheumatic, it was believed to be subacute. He recovered and went on with his work as usual. Three months before admission he had cough with frothy expectoration, and soreness under the lower end of the sternum. One month later he began to suffer from shortness of breath. He had not at any time noticed any diminution in the daily quantity of urine discharged. On admission he complained of dyspnœa, cough, and soreness in the region of the xyphoid cartilage. Physical examination revealed a murmur with both sounds of the heart, and heard with greatest intensity over the aortic valves. The area of cardiac dulness was increased. The urine was acid, had a specific gravity 1020, and did not contain albumen.

The question arose whether or not the cardiac lesions found depended upon endocarditis occurring two years ago. If so, it was exceptional—for cardiac lesions, sufficient to develop marked physical signs, originating in as recent an attack of endocarditis, were regarded as rare.

◆

PROMOTIONS AND APPOINTMENTS IN THE UNITED STATES MARINE HOSPITAL SERVICE.—At the regular examinations held by the Marine Hospital Service, in New York, June 21st to 25th, the following promotions and admissions were made:

Assistant Surgeon John Godfrey, to be Passed Assistant Surgeon; Assistant Surgeon F. H. Brown, to be Passed Assistant Surgeon.

Dr. John Guiteras, of Philadelphia; Dr. Wm. A. Wheeler, of Evansville, Ind.; Dr. J. A. Benson, of Hoboken, N. J., and Dr. C. E. Banks, of Portland, Me., passed the examinations, and were admitted to the service as Assistant Surgeons.

Dr. Benson has been ordered to report at Baltimore, for temporary duty. Dr. Wheeler is ordered to New York City; Dr. Banks to San Francisco, and Dr. Guiteras to St. Louis.

Progress of Medical Science.

ABDOMINAL SECTION FOR PURPOSES OF DIAGNOSIS.—Dr. J. H. Stallard (*San Francisco Western Lancet*, May, 1880) relates a case of rapidly growing tumor in a man 41 years old, where an exploratory laparotomy was performed. Antiseptic rules were scrupulously observed. An incision five inches long was made in the linea alba, terminating an inch below the umbilicus. The stomach, slightly distended with flatus, appeared at the upper part of the opening, and the omentum below. The latter was of a deep port-wine color. There were no adhesions. The hand readily passed between the tumor and the stomach and liver above, and the intestines and omentum below. The growth was attached deeply to the root of the mesentery in front of the great vessels. There was no distinct pedicle. The tumor was firm to the touch and smooth upon the surface. A thorough examination was made by the assisting physicians, and it was unanimously decided that an attempt at removal would prove immediately fatal. The wound was therefore carefully sponged, and closed with silver sutures. The dressing was that of Lister. The patient recovered without a bad symptom. At no time did the temperature exceed 100° F., and on the third day it was normal. The wound was found dry and well united on the fifth day. On the ninth the ligatures were removed. On the fourteenth day he sat up and took his usual food. He was now quite as well as before the operation.

Dr. Stallard adds that, although unsuccessful as a curative proceeding, the above case at least suggests the adoption of abdominal section as a means of diagnosis in a number of cases, where the nature of the internal disease cannot be determined by ordinary means. Under spray and with proper antiseptic precautions, there would seem to be little or no danger in making exploration for internal herniæ, intussusceptions, impacted gall-stones, fibro-cystic and other growths. We may incidentally mention the fact that Dr. Stallard's idea is not a new one. Similar exploratory incisions have for some time past been in vogue, especially in Germany, where the number of such operations is already quite large. In our country, however, cases of this kind have not hitherto been frequently reported. Perhaps they were not successful. At any rate the surgeon is justified in undertaking this operation in certain exceptional cases, and when we have gained more experience in this matter, the death-rate may be appreciably diminished.

PUSTULAR RASH FROM SHEEP-WASHING.—M. Steel (*Brit. Med. Jour.*, May 8, 1880) relates the following case. In May, 1879, a gentleman, fair, tall, robust, a very distinguished athlete, presented himself to Mr. Steel, with the front and inner side of his left arm from the shoulder to the wrist, and the left side of the chest and upper part of the abdomen, covered with a pustular rash, the character and localization of which puzzled him considerably. It was at length elicited that, about a fortnight before, he had assisted as an amateur in a day's sheep-washing. In the course of this operation the sheep is grasped by the left hand and supported on its back against the left side of the washer, standing nearly to the middle in water, while the right hand is engaged in rubbing away the clay and dung with which the wool of the belly is often clotted. It was also ascertained that the sheep had recently been dipped in a sheep-dipping composition, probably containing mercuric bichloride or arsenic, for the destruction of tick and other parasites. The cause of the eruption was now clear, though the patient had no suspicion of its origin. He wore a thin flannel shirt and duck trowsers. The shirt became saturated with water from the wet sheep, but was not otherwise immersed. The right hand, being constantly washed with fresh water, escaped. His fellow-laborers, wearing their usual thick clothing, also remained unaffected.

Acute Miliary Tuberculosis in the Adult.—Four cases of this kind were recently observed at the King's College Hospital, and the following remarks conclude the account given of them in the *Brit. Med. Jour.*, May 8, 1880. These cases are of considerable interest as illustrations of the difficulty which surrounds the diagnosis of acute tuberculosis in the adult from other febrile affections, more especially from typhoid fever. Thus the more or less obscure history, the absence or equivocal character of the pulmonary physical signs, the presence of abdominal symptoms or diarrhœa, the absence of marked dyspnœa (in one case at least), united in greater or less degree and in varying combination to render exact diagnosis exceedingly difficult. Although differing individually in the precise grouping of their symptoms, all the cases presented one common salient feature: their pulse-temperature ratio was markedly disturbed. For example, in one case, with a temperature which never exceeded 102° F., the pulse varied from 110 to 136 per minute. Again, in another case, while the temperature varied from 101.4° to 102 , the pulse ranged from 130 to 156 per minute. A similar condition was observed in the other two cases; and it was noticeable that although, in one of these, the temperature took a somewhat higher range (104° to 105°), the pulse also varied disproportionately, varying from 130 to 150 per minute. Wunderlich had especially insisted on this point in the diagnosis of acute tuberculosis; and it seems evident, from the cases described, that it might prove of great value in the recognition of the more obscure cases of this disease.

Fatal Herniotomy.—Two cases of herniotomy, fatal in consequence of hemorrhage from abnormally distributed obturator arteries, are reported to have been observed at the Sussex County Hospital (*Brit. Med. Journ.*, May 8, 1880). Case I. was that of a woman aged 62, who had a swelling in the left groin for four months. When first seen she was in a collapsed condition, with dry, brown tongue, and frequent stercoraceous vomiting; pulse 100, feeble. Her expression was anxious; she complained of pain at the umbilicus; there was a small hard swelling at the left femoral ring, without impulse on coughing. A few hours after admission, herniotomy was performed. A small knuckle of intestine was found very tightly constricted at Gimbernat's ligament; the ligament was incised, but, before the bowel could be reduced, a second stricture, formed by the sac itself, had to be divided. When Gimbernat's ligament was divided, free bleeding occurred, but this was apparently controlled without difficulty. The day after the operation, some hemorrhage was detected from the wound, and, as it could not be controlled, the wound was again opened and the bleeding point searched for, but without success. The patient gradually sank, and died on the third day after the operation. At the necropsy the neighborhood of the wound of incision was found infiltrated with blood, which extended beneath the peritoneum, as high as the umbilicus. The hemorrhage was found to proceed from the complete division of the obturator artery, which arose from the external iliac in common with the epigastric, and crossed over the femoral sheath and along the inner margin of the crural ring.

Case II. was that of a woman aged 64, who had had a rupture five or six years, but had always been able to return it herself. She had never worn a truss. On admission, four days after her inability to return it, there was a hard swelling, about the size of a walnut, in the position of the femoral ring, without impulse, and irreducible. Soon after admission, she vomited a material exactly resembling thick liquid fæces in appearance and smell. Herniotomy was performed under anæsthetic mixture. A small knuckle of bowel and a piece of omentum, which were found in the sac in a somewhat congested condition, were returned without difficulty, only a very slight nick in Gimbernat's ligament being needed to relieve the stricture. No hemorrhage occurred at the time of operation. She was apparently much relieved by the operation, and passed a good night, but the following evening she began to complain of a frequent desire to micturate, and of some tenderness of the abdomen, and on the day but one after the operation she showed signs of severe collapse, and vomiting recommenced. The collapse increased, and she died early the following morning. There was no hemorrhage from the wound after the operation. At the necropsy, eight hours after death, the wound was found healthy in appearance externally, without any ecchymosis of the surrounding skin, but on opening it out some clotted blood appeared, and on tracing this back, a large mass of clot was found in the subperitoneal tissues surrounding the wound, and in the neighboring parts of the pelvis. It was found that the obturator artery, which arose from the external iliac in common with the epigastric and passed over the crural ring on its course to the pelvis, had been partially divided, probably at the time when Gimbernat's ligament was nicked. The obturator artery on the opposite side did not arise from the external iliac, and was probably normal in origin. The reporter added that the interest of the two cases centered, of course, in the abnormal distribution of the obturator artery, in each case the cause of death being its accidental division, which was in the one case partial, in the other complete.

Sterility in Women.—Dr. Harry L. Sims read an interesting paper on the above, at a recent meeting of the San Francisco Obstetrical Society (*Western Lancet*, May, 1880). McIntosh was said to have been the first to begin proper treatment by dilating the cervical canal with bougies. Then came Sir James Y. Simpson, who followed the same idea, by incising the cervix to make the canal permanently open. But these procedures did not often lead to the cure of sterility. The sterile condition, according to Sims, may be caused by one of many things, such as polypus, fibroid tumor, some malposition, a painful dysmenorrhœa, a contracted cervical canal, a flexed cervix, abnormal utero-cervical secretion destroying the vitality of the spermatozoa, etc.

Three questions must be determined at the outset, in order to secure scientific treatment: 1. Does the semen contain spermatozoa? 2. Do they obtain access to the utero-cervical canal? 3. Are there any secretions in the canal which will poison the spermatozoa? If no spermatozoa are found in the semen, the uterine condition needs no treatment. If spermatozoa do exist in the semen, but do not enter the cervical canal, then arises the question of the propriety of an operation. If, however, the spermatozoa do enter the canal, then, as a rule, no surgical interference will be necessary. Dr. Sims is in the habit of examining microscopically small quantities of the secretions found in different parts of the genital tract. For this purpose he employs a small rubber syringe, with a long glass nozzle, the point of which is in the shape of an inverted cone.

Sometimes repeated examinations become necessary. The normal secretion of the cervix, he says, should be as clear and translucent as the white of an uncooked egg; when this secretion is full of little snow-white specks, it is always inimical to the viability of the spermatozoa. While treating the patient, he always examines the cervical mucus every few days. At the beginning the spermatozoa are all found to be dead. Some time afterward, some will be alive and the rest dead; then, later on, nearly all will be alive; and when, finally, the spermatozoa are all found alive, the case may be pronounced cured. A great deal of patience, however, will be necessary before such a result is obtained.

Dr. Sims emphasizes one indisputable fact, and that is that the spermatozoa must reach the uterine cavity in order to produce pregnancy, and they must there find a secretion which will not be inimical to their viability. His method of incising the cervix, which is essentially that of his father, Dr. J. Marion Sims, is described, and several cases related. The paper closes with the statement that Dr. Sims has operated, during the past seventeen months, on nineteen cases of uterine flexions, for sterility. Of these cases, thirteen have already resulted in pregnancy.

TAPPING PULMONARY CAVITIES.—Dr. Thompson, of London, in a paper on this subject (*Virginia Med. Monthly*, June, 1880), makes the following remarks: Pulmonary cavities may be broadly classed into two groups: 1, those which are found in the upper lobe of the lung, and which may be denominated *phthisical;* and 2, those which are formed in the base of the lung, and which are generally *pneumonic.* The first group—apicial or phthisical cavities—occupy preferably the upper lobe, secrete (?) matter of a peculiar nature, non-fetid, septic, but seldom distinctly purulent, although under the microscope degenerated pus-cells may be found. The peculiar characteristic nature of the matter is shown by its property of producing tubercular infection, when locally applied to pulmonary tissue. The second group—basic or pneumonic cavities—occupy only the lower parts of the lung, secrete a purulent, often a gangrenous matter, of overpowering fetor, which, when transferred to other parts of the lungs, results, not in tubercle, but in pus. The first kind of cavity is invariably associated with firm and complete adhesions of the pleural surfaces in the neighborhood of the cavity. With the second form of cavity the adhesions are by no means so complete; bands of fibres may only tie down the opposite pleural surfaces, or the cavity may be associated with an empyema and absence of adhesion—a condition by no means rare. An illustrative case is then cited, and after some further considerations the following conclusions are presented: 1. Except for the introduction of local remedies, the puncture of an apex cavity can hardly be expected to lead to any good result. 2. The puncture of a basic cavity is demanded if the secretion be fetid, provided there are reasonable grounds for supposing that the pleural surfaces in the neighborhood of the cavity are sufficiently adherent to prevent artificial pneumo-thorax. 3. The advantages to be gained by the operation are the ventilation of the cavity and the diminution of fetor, and especially the prevention of matter passing over to, and infecting the sound lung.

STATISTICS OF 250 CASES OF CANCER OF THE BREAST.—Dr. Oldekop publishes an extended report of 250 cases of carcinoma of the mamma, which were treated in Prof. Esmarch's wards in Kiel between the years 1850 and 1878. Of these cases, 21 were not operated on. Of the remaining 229, 23 died in consequence of the operation; in 109 the tumors returned; in 43 the tumors did not recur, some of these patients being still alive, while others have died of intercurrent diseases; in 54 the patients were lost sight of after they left the hospital. The majority of the patients were between 46 and 50 years of age; the average age at which the disease first made its appearance was 48.4 years. Of the patients, 208 were married, and 30 single. Of 103 who had borne children, 36 had suffered from puerperal mastitis. In 9 cases the tumor developed from nodules left by previous mastitis. The statements with regard to previous injury were uncertain. The cancer affected the right breast in 123 cases, and the left in 102. The upper and outer half of the gland was most frequently affected. In 11 cases hereditary predisposition existed, and in 60 cases it could be positively excluded. In 31 cases in which the axillary glands were not involved, the average duration of life after the operation was 45.1 months; period of freedom from relapse, 6 months. In 57 cases in which the glands were involved, the average duration of life after the operation was 34.8 months; period of freedom from relapse, 2.5 months. The average duration of life from the first appearance of the disease was, in the cases not operated on, 22.6 months, and in the cases operated on, 38.1 months. On 225 patients, 287 operations were performed, with 23 deaths. Out of 184 operations performed before the introduction of Lister's method, there were 16 deaths, a mortality of 8.7 per cent.; out of 77 performed under antiseptic precautions, there were 7 deaths, a mortality of 9.1 per cent. The average period of convalescence was formerly 5.2 weeks, but after the adoption of Lister's methed it fell to 4.6 weeks. In 40.9 % of the patients the entire mamma with the glands was removed (mortality, 13 %). Of the 23 deaths from the operation, 12 were due to accidental surgical diseases, 4 to collapse and secondary hemorrhage, 1 to pneumonia, and 6 to causes that could not be clearly ascertained. Erysipelas occurred 15 times, and proved fatal in 5 cases. In 46.4 % of the cases the recurrent tumors appeared within the first three months after the operation; after that period the recurrences diminished steadily in frequency, and after one year they only occurred in 18 cases, or 16 %. A reappearance of the tumor after three years' interval was only observed in one case, and in that there was some room for doubt. Hence three years may be regarded as the limit for the appearance of recurrent tumors. If this be accepted as correct, 23 of Esmarch's cases may be regarded as definitely cured. The seat of recurrence was far more frequently the cicatrix than the axilla; and when the operation was limited to the removal of axillary glands, the recurrent tumors generally appeared in the axilla. Dr. Oldekop concludes his paper with brief synopses of the histories of the 250 cases.—*Langenbeck's Archiv.*, vol. 24.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, July 31, 1880.

PHYSICIAN AND DRUGGIST.

The relations which should exist between physician and pharmacist will always interest both parties in the discussion. More especially will this be the case so long as there appears to be such a wide divergence of opinion as to mutual rights. It would seem, considering the amount of ventilation which the subject has received, that there would be some line of demarcation agreed upon that would separate the two professions; that would mark the limits of the functions of each, and would show where one commenced and where the other ended. But we seem as far as ever from a settlement of respective claims. The reason for this probably is that there is not much disposition on either side for that spirit of compromise which would allow of a calm and unprejudiced adjustment of differences. It is quite necessary that we should come to this point as speedily as possible, inasmuch as there is developing on both sides a belligerent attitude which is ominous of much trouble in the future.

With a view of fostering a better understanding of the question, and of reconciling apparently contending interests, we propose to throw out a few suggestions in that spirit of impartiality which must invite a calm consideration of the points at issue. We must start with the assumption that the physician and pharmacist have so many interests in common that they cannot afford to quarrel. They are naturally helpers of one another, and require mutual support. The real question should be how the latter end can be best accomplished. All discussion should bend in that direction.

In order to understand the true position of affairs it is necessary, in the first place, to look at the difficulties which appear to be in the way, and, secondly, to find the means of overcoming such obstacles.

In olden times physician and apothecary were combined, and the doctor's saddle-bags were as indispensable to his outfit as was the horse he strode, or the lancet he wielded. He was dispenser as well as prescriber, and was happy in being the factotum in the sick-room. Except for the veritable grandma, who so constantly beset his pathway with her favorite teas, there was no one to interfere with his just prerogative, none to question the means used for the cure of the patient. The progress of the healing art, and the necessities of the situation which grew out of it, gradually separated the functions of prescriber and compounder until they became respectively associated with two distinct professions. The cultivation of each of these professions has progressed to such a degree that they are becoming more and more widely separated, the practitioner in each requiring a special and independent training. If the representative of each is contented to attend to his duties, there would be no possible trouble, no question whatever regarding individual rights. But that the contrary is the case no one can deny, and hence the discussions which have ensued regarding mutual relations.

Without any danger of being charged with partiality toward the physician, we feel warranted in saying that in regard to individual rights he is more sinned against than sinning. Although he cannot be entirely exonerated from all blame, he is, as regards opposition to the claims of the pharmacist, more on the side of the defensive than on that of the offensive.

In discussing the difficulties in the way of a proper understanding of mutual dependency we may commence with those more directly chargeable to the druggists themselves. First and foremost of such is the practice of counter-prescribing, now becoming so common among a large class of these gentlemen. This is so clearly trenching upon the legitimate province of the physician that no argument is needed to prove it. We are aware that it is stated, on apparently unquestioned authority, that counter-prescribing is not a prevalent practice; but we know to the contrary. In fact, every physician can point to two or three so-called respectable pharmacists in his neighborhood, who not only deliberately prescribe over the counter, but encourage the practice with their subordinates. It is impossible to estimate the abuse to which such methods of prescribing are liable, the injury they inflict upon the patient and the damage which they cause the physician. In fact counter-prescribing is such an important element of antagonism against the physician, that it can safely divide the honors with the indiscriminate prescribing at the clinics. There are druggists in this city who have as large a consultation for venereal diseases as many of our specialists, yet have no further qualifications for practice than are comprised in a license to compound prescriptions and in the enjoyment of the very questionable title of "Doctor" among their customers. And yet the patients of these prescribers are abundantly satisfied to pay exorbitantly for cubebs, copaiba, mercury, and iodide of potash, in consideration that advice is given gratis. By some uncharitable young practitioners of medicine this may be styled cheating the doctor of his fee, but by the enterprising counter-prescriber it is generally looked upon as a stroke of business.

Another abuse of the prescription business, and one which may be looked upon as a phase of counter-prescribing, is the offering of gratuitous advice concerning the contents and uses of the prescriptions of physicians. The self pride of the compounder is attacked when the messenger with a prescription asks him if such remedies are proper for such a disease as the patient is supposed to be suffering from. The evasiveness of the answer not uncommonly resolves itself into an injunction that the messenger shall not repeat the opinion expressed concerning the writer of the prescription. We do not wish to say that this is a very common practice, but it is indulged in with sufficient frequency to warrant notice in this connection.

The same may be said of the practice of substituting one drug for another in a prescription, or of omitting altogether what is considered by the prescriber as an essential element in his recipe. Diminishing the dose of a drug without consulting the physician, on the possible supposition that the latter has made an error, is another method of unfair dealing on the part of the compounder. But worse than all is the recommending of a patent medicine in place of that duly prescribed by the family medical attendant. Not a few respectable pharmacists have preparations of their own, which range in importance from tooth pastes, and proprietary perfumes and extracts, to cough mixtures, pile cures, fever and ague remedies, and kidney teas. Human nature scarcely expects that these articles will be modestly placed in the background until they are sought for by the customer; and hence the druggist, very innocently, perhaps, interferes with the prerogative of the legitimate prescriber for disease.

These are, however, little abuses in the business of compounding which the physician and prescriber is expected to condone, as otherwise he might, in the opinion of some advanced innovators, interfere with the legitimate business of the ordinary pharmacist. We name these as a type of the abuses for which the druggists themselves are to blame, but we are happy to say that there are many pharmacists who are above suspicion in those respects, and consequently beyond criticism. We would that they were more numerous. As it is, they are hardly sufficient in number to make more than exceptions to the general rule, and give to us a tangible foundation upon which to build our hopes of reform. In a succeeding number we shall continue the discussion of this subject.

HUMAN AND BOVINE TUBERCULOSIS.

The question of the relation which the bovine tuberculosis holds to the human, is one that is again deservedly awakening general attention. When it is remembered that in some places nearly five per cent. of cattle are affected with tuberculosis, the practical, as well as the scientific importance of studying the subject will be readily acknowledged.

There are two points which need special investigation and definite settlement. These are, first, the identity of tuberculosis of cattle with that in man; and, second, the possibility of man's being infected with the bovine disease by using the flesh or milk of cows affected with it.

Bovine tuberculosis (the pearly sickness of the Germans) has always appeared to have pathologico-anatomical characters considerably different from the human disease. The tuberculosis eruption, in the former case, affects by preference serous membranes, especially those of the pleura and peritoneum. It has been called, on this account, a serous tuberculosis. There is, furthermore, a breadth and pedunculated arrangement to the serous nodules which is quite characteristic. They are sometimes arranged along the membrane like strings of pearls. The French call the disease "pommelière," from the potato-like clusters in which the nodules group themselves. The bronchial and abdominal glands are also characteristically enlarged, each containing several distinct, round tuberculous masses. The tubercles, when they have thus appeared, have a tendency to calcify, rather than soften, as in human tuberculosis. Microscopically, they are said by some to be identical with human tubercles. Klebs, Schüppel, Fuchs, and others, take this view. Virchow, however, asserts that the pearly nodules are little lymphosarcomata, and considers the disease essentially different from genuine tuberculosis.

The evidence that the diseases are identical comes more from experimentation by inoculation and feeding than from histological study. Thus it is now positively ascertained that inoculating bovine tuberculous matter in lower animals, such as sheep, swine, rabbits, and dogs, or feeding the same with the flesh or milk of diseased cows, will produce tuberculosis in these animals. And most authorities are agreed that this is a genuine miliary tuberculosis, like that obtained from inoculating human tubercle. Schüppel, Zürn, and Klebs are very positive on this latter point. Furthermore, Klebs asserts that by inoculating calves with human tubercle he has produced the characteristic pearly eruptions of the bovine disease. All this points pretty strongly to an identity between the two diseases. There are some facts, however, which oblige one to hesitate before adopting a positive opinion.

Gerlach fed twenty-seven animals upon the flesh of tuberculous cows. Of these, only eight presented lesions which could be considered tuberculous. Virchow fed fourteen small animals, of different kinds, upon the milk of a cow supposed to be tuberculous. A large number of these animals showed the tubercular eruption upon autopsy. When the cow was killed, however, its lungs were found filled with echinococci cysts, but had no tubercles at all. Finally, a series of cases has recently been reported in *The Lancet*, by Dr. Charles Creighton, which have an important bearing upon the subject. These cases, during life, were considered to be those of ordinary acute miliary tuberculosis. On post-mortem examination, however, Dr. Creighton describes them as all having the peculiar appearances of the pearly sickness of cattle. He infers, therefore, that the two diseases, bovine and human tuberculosis, are not identical, but that they are intercommunicable. The evidence is not sufficient to settle the point, and we must leave it here for future investigation. But the probabilities of the whole are that bovine tuberculosis, whether identical with human, or not, can be communicated to man. This probability should furnish every stimulus to physicians and pathologists to investigate the subject further.

Reviews and Notices of Books.

Atlas of Human Anatomy, containing 180 large plates, and arranged according to Drs. Oesterreicher and Erdl, from their original designs from nature, etc., etc., with full and explanatory texts. By J. A. Jeançon, M.D. Cincinnati: A. E. Wilde & Co.

On the appearance of Part I. of this admirable atlas we took occasion to speak in the highest terms of praise concerning the accuracy and artistic elegance of the figure represented. Since then we have received Parts II., III., and IV. of the series, containing a collection of life-size dissections. The plates before us represent the superficial arterial supply of the head, neck, and also of the deep arterial supply of the same regions, together with the thorax and the branches of the popliteal as they ramify over the knee-joint. The nerves of the neck and thorax are represented in another life-sized outline drawing, which, like the figures already mentioned, is a marvel of artistic beauty, a rare example of anatomical accuracy, and a wonderful exhibition of detail work.

In the same series of plates is seen the arterial supply of the upper extremities, showing the deep and superficial palmar arch and the anatomical relations of the same.

Osteology is also represented—the base, floor, and vertical section of the skull are shown with typical vertebræ; also a section of the lower jaw, the bones of the hand and of the foot, and, lastly, sectional views of the shoulder and elbow joints.

As we have already said, all these representations are life-size. The plates alluded to—of the arteries and nerves—could hardly be more perfect, but in those of the bones, ligaments, and joints, there is room for much improvement in detail drawing. For the most part, the bones are very coarsely drawn, and do not give the reader an accurate idea of the facets, grooves, and prominences which play such an important rôle in the anatomical relations of these parts.

Photographic Illustrations of Skin Diseases. By Geo. Henry Fox, A.M., M.D. New York: E. B. Treat & Co. 1878.

The completion of this atlas in twelve parts gives us an opportunity, in a general way, of speaking of the faithful and painstaking manner in which the author has performed his work. On former occasions we have noticed the different parts as they appeared, and our readers have already an idea of the plan of representing the different typical forms of skin disease. We say typical, for the reason that Prof. Fox has succeeded, in almost every instance, in presenting the leading features in each class of cutaneous eruption. The opportunities for making selections have been very great, and he has certainly improved them in a way that will be eminently satisfactory to the student and the practitioner.

The time has gone by for prosy descriptions of skin lesions, and photography comes to our aid in presenting the actual appearances. When we add to this the effect of color we have nothing to wish for in the way of making the study of skin diseases a pleasant and profitable pastime.

As a whole, the work is an invaluable contribution to the specialty, and is especially adapted to the wants of the general practitioner.

The Throat and its Functions in Swallowing, Breathing, and the Production of the Voice. By Louis Elsberg, A.M., M.D. New York: G. P. Putnam's Sons. 1880. 8vo, pp. 60.

This book contains a lecture delivered by the author in the course of popular scientific lectures under the direction of the New York Academy of Sciences. The subject is treated of in a popular style, being chiefly intended for non-professional readers. The book is gotten up in good style, but would have been rendered more valuable had there been an index.

Students' Aids Series. Aids to Chemistry. Part I. Inorganic—The Non-Metallic Elements. Part II. Inorganic—The Metals. Part III. Organic. By C. E. Armand Semple, B.A., M.B., Cantab., M.R.C.P., Lond. New York: G. P. Putnam's Sons. 1880.

These three little books consist of abstracts of lectures delivered by the writer to his pupils. As aids to those commencing the study of chemistry, they will be of advantage; but we would strongly deprecate the use of such books by advanced students, or those who intend passing an examination on the subject, as it is only treated of in a cursory manner, and larger works should be made use of, in order to obtain a thorough knowledge of chemistry.

Bible Hygiene or Health Hints. By A Physician. Philadelphia: Presley Blakiston. 1880. 12mo, pp. 249.

The object of this work is to render popular the subject of hygiene. The Bible is largely quoted throughout the work, mainly to show that the subject of sanitary science is treated of there, and also that a great many of the ideas contained in that book are carried out at the present day. The book can be read with benefit even by medical men, as it contains much valuable information.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 9, 1880.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

CHELOID GROWTH OF EAR.

DR. POST presented a specimen of cheloid growth of the ear following the perforation of the lobe of the ear for an ear-ring. A small growth of the same character existed in the lobe of the opposite ear and was also excised. After the ear-rings were inserted a number of years ago there was a considerable amount of inflammation of the parts.

In the present instance the ear-rings were of the finest gold, purchased of a leading jeweller, who made the necessary perforations. In answer to a question from Dr. Satterthwaite, Dr. Post stated that cheloids in the ear were not liable to return after thorough extirpation.

DR. SATTERTHWAITE referred to a case in which he removed a cheloid from each ear three years ago, and in which the disease returned within a year.

RUPTURE OF THE BLADDER FROM A FALL.

DR. PEABODY exhibited a specimen of rupture of the bladder. It was removed from the body of a man twenty-three years of age. Three days before his death he fell down-stairs, striking upon his back. From this time on he had severe pain in his abdomen and frequent vomiting. The next day he entered the New York Hospital with all the symptoms of peritonitis. His temperature varied between 100° and 102.8°, and his pulse between 112 and 120. He sank steadily, and died three days after the accident. All the time that he was under observation he suffered from retention of urine. When drawn by the catheter it contained much blood.

Autopsy, twenty-two hours after death.—There was general peritonitis, which was most intense in the neighborhood of the cæcum. The peritoneum contained 350 c.c. of reddish fluid, with many flakes of lymph. This condition was fully explained by inspecting the specimen. About half an inch to the right of median line was a rent in the bladder. It was two inches long and extended to within an inch of the anterior abdominal wall. Its edges were granulating. There was nothing else of interest in the autopsy. The case was interesting as showing how slight internal violence could rupture a bladder which presumably was full.

ACUTE ULCERATIVE ENDOCARDITIS.

DR. PEABODY presented a specimen of the above with the following history:

The patient was a woman, 43 years of age. Three weeks before death she twisted her foot while going upstairs, and caused a fracture of the left fibula, 1½ inch above the ankle-joint. For this trouble she entered the New York Hospital six days after the injury. On admission she had pneumonia in the upper part of the right lung, and soon becoming delirious, she, by constant tossing about, converted her simple fracture into a compound one. The pus burrowed in both directions and finally involved the ankle-joint. During the next ten days she had symptoms of septicæmia and died exhausted two weeks after admission.

Autopsy, twenty-four hours after death.—The wound was as described above. There was meningitis, with extensive purulent exudation over both base and convexity of brain. The upper lobe of the right lung was in condition of gray hepatization.

The *heart*, which was shown you here, was normal in size. The muscular tissue was normal. The valves on the right side were normal. On the auricular surface of both segments of the mitral valve, running along their free border, was a loss of endothelium sufficient to make distinct ulcerations. A similar condition existed on the ventricular surface of two segments of the aortic valve, except that the ulcers were irregularly circular and rather more extensive. One of them was at the junction of two segments of the valve, and both ulcers had loosely attached to them, at the time of making the autopsy, large masses of firmly coagulated fibrine, upon whose roughened surface, in places recently coagulated, blood was to be seen.

Each kidney and the spleen contained a recent hemorrhagic infarction whose centre in each case was purulent.

Upon microscopic examination of the kidneys a few colonies of micrococci were found in the vessels and some apparently loose in the kidney tissue. Teased specimens, removed from the ulcers in the heart and also from the coagula attached to some of the ulcers, showed large colonies of micrococci. Sections of the anterior flap of the mitral valve, which you observe has been cut away, showed the condition of the site of the ulcer to be that of recent inflammation, and also showed numerous colonies of micrococci in the tissue of the valve. In the lungs, also, micrococci were found in a large vessel. There were no micrococci found in the brain.

FAT EMBOLISM IN LUNGS AFTER FRACTURE; ITS SIGNIFICANCE AS A PATHOLOGICAL LESION.

DR. PEABODY lastly exhibited a microscopical specimen of fat embolism in the lungs after fracture. The patient from whom the specimen was removed was a young man, aged 22 years, who fell down a hatchway, sustaining a simple fracture of the right tibia and extensive fracture of the skull, causing intra-cranial hemorrhage from middle meningeal artery, and death on the third day. In answer to a question from the President, Dr. Peabody stated that sometimes fat emboli would of themselves cause death, but as a rule their presence was not of much clinical importance.

DR. HOWE referred to a case of transfusion of milk in the St. Francis' Hospital, in which death at the end of five hours after the operation was charged to fat emboli in the heart and lungs. About seven ounces of milk were injected into the long saphenous vein about 11 A.M. The patient walked down to the ward, took his dinner without trouble. About three o'clock, became comatose, and died an hour afterward.

RUPTURE OF THE BLADDER FROM STRAINING.

DR. L. BOLTON BANGS presented a specimen of rupture of the bladder.

The patient from whom the specimen was taken, was a male, 42 years of age, of temperate habits, and with the exception of his genito-urinary troubles was usually well. About fifteen years ago, while on horseback, he was thrown forward upon the pommel of his saddle, and his urethra sustained an injury, which, within two years after, caused frequent and painful urination and marked diminution in the size of the stream. He went to Edinburgh and sought relief at the hands of Prof. Syme. The latter found the urethra to be narrowly strictured at about 4½ inches from the external meatus, and treated it by dilatation. The calibre of the urethra at the time of beginning treatment was not stated, but the patient was discharged with directions to pass a nearly straight metallic instrument of the size of 16 French, at frequent intervals all the rest of his life. During the succeeding years he had occasional attacks of retention of urine, which were always relieved by the catheter. His condition gradually grew worse, and in the year or two preceding his death he had had several hemorrhages, presumably from the bladder; his urination was accomplished in a small stream, with great straining, the urine being mixed with stringy mucus, and he had frequent attacks of retention of urine, which sometimes were relieved by the catheter, and at others by hot baths and opium For a month previous to his death no instrument could be made to pass the stricture; and a *fortnight* before, he had a hemorrhage which lasted a week. He had come to look upon these attacks of retention and hemorrhage with indifference, and being a man of considerable fortitude, had treated them himself, or "waited till they passed off." He had had no surgical attendance since that of Prof. Syme. The writer was summoned to him in great haste about 8.30 A.M., with the statement that while he was straining to urinate as usual, "something in his bowels had given way, and he was now in great pain." When seen an hour after the accident, his face was pallid, extremities cold, and drenched in sweat; he was lying on his back with his knees drawn up, and complaining of great pain in his abdomen, which was tender on palpation. His pulse was 120 and very feeble. Temperature (axilla), 102½°. Under the free use of stimulants and morphia he rallied sufficiently to give, with the aid of his wife, the foregoing meagre history.

Examination of his urethra showed an impassable stricture at 4½ inches from the external meatus. Aspiration of the bladder failed to withdraw any urine.

He continued to fail, and died ten hours after the accident. At the autopsy, which was made three hours after death, the abdomen only was opened. There were the usual evidences of general peritonitis, and the fluid, in which were flocculi of lymph, had a very slightly urinous odor. The intestines were agglutinated to the summit and body of the bladder, and on lifting them, a *pouching* of the posterior wall of the bladder was seen. This pouch was to the left of the median line, beneath the line of reflection of the peritoneum, and at its apex was a minute irregular opening communicating with the cavity of the bladder. At and around the opening the pouch consisted of peritoneum only. The bladder was removed and opened by an incision from its summit to and including the prostate gland. In its cavity was about half an ounce of purulent, bloody urine. Its several coats were notably hypertrophied, being three-fourths of an inch in thickness. The mucous coat was of a brownish color, soft, and everywhere covered with a layer of muco-pus. In the posterior wall of the body, an inch to the left of the median line and midway between base and summit, was an irregular circular ulceration, with complete destruction of the mucous, submucous, and muscular coats. The peritoneal coat at this locality was thickened, except at the inferior segment of the cavity where it was of extreme thinness, and here was the opening alluded to forming the communication between the bladder and pelvis. On the same plane, in the median line, and extending to the right of it, was another irregular lop of tissue, forming a cavity in the muscular coat of an inch in circumference and containing a little pus, which flowed into the bladder on pressure from without. At the base of the bladder were five small calculi, the largest not bigger than a hemp-seed, each in a depression in the thickened mucous membrane of corresponding size. On the floor of the prostatic urethra, to the left of the veru montanum, was an opening 5 mm. in diameter, communicating with a cavity in the left lobe of the prostate gland, containing pus and two or more calculi. In the right lobe of the prostate was a similar cavity containing pus and calculi, and opening into the urethra by two minute holes.

The urethra and kidneys could not be obtained for examination.

Dr. Howe suggested that in such cases, when a diagnosis could be made, it would be good practice to cut down upon the bladder, sew up its rent, wash out the pelvic cavity, and take the chances.

BULLET IN HEAD OF TIBIA SEVENTEEN YEARS.

Dr. Delavan presented a bullet removed by Dr. Markoe from the upper portion of the tibia of a soldier who had been wounded at the battle of Chickamauga, seventeen years ago. The ball entered the posterior aspect of the leg, about an inch and a half below the head of the tibia. Shortly after the reception of the wound, a sinus formed upon the anterior aspect of the leg and continued to discharge up to the time of the operation. The general symptoms were those of chronic disease of the bone. In the neighborhood of the ball a small quantity of gunpowder was found, as, also, the remains of some clothing. The ball itself was encrusted with a calcareous deposit from the pus in which it had been bathed for so many years.

BUCKSHOT IN HEART OF A DOG.

Dr. Delavan also presented the heart of a setter dog, in the muscular substance of which there were nine large-sized buckshot. As the dog had not hunted for a number of years it was fair to presume that the shot had been carried for a long period.

THROMBOSIS OF PULMONARY ARTERY.

Dr. Heinemann presented a specimen of thrombosis of the right pulmonary artery. The case was one of erysipelas of the face, followed by abscess of the left side, giving rise to phlebitis of the left jugular vein, and plugging up of the same with thrombosis of the right pulmonary artery, and consequent infarctions of the lung.

EXCISION OF ANKLE-JOINT.

Dr. Howe presented a patient upon whom he had performed subperiosteal excision of an inch and a half of the tibia and fibula, and the upper portion of the astragalus. The shortening was two inches, but this was compensated for by the wearing of an extra pad under the heel. The motions of the new joint were quite perfect.

DIAGNOSIS OF VAGINITIS AND METRITIS, BY MICROSCOPIC EXAMINATION OF URINE.

Dr. C. Heitzmann called the attention of the society to the differential diagnosis between urine of the male and the female. In the latter, he stated, that by the microscope almost always vaginal epithelia were seen, except in urine of virginal persons. The presence of pus-corpuscles, with a larger amount of epithelia of the vagina, both the upper flat and the deeper cuboidal, which latter often exhibit endogenous formation of pus-corpuscles, admitted of the diagnosis of *vaginitis*. Larger caudate and sharply angular epithelia were present on the vaginal portion of the uterus; if such epithelia were present in the urine, together with pus-corpuscles, the diagnosis *cervicitis* could be made. Columnar, ciliated epithelia, either in toto or broken apart into smaller elongated pieces, some of which also may be ciliated, appeared in the urine, whenever *metritis* was present. Pus-corpuscles discharged from the uterus were often ciliated. Care should be taken to guard against errors due to the presence of thin pseudopodia or of attached bacteria. Such ciliated pus-corpuscles were quite characteristic in the urine, in cases of metritis. The presence of connective-tissue shreds always indicated ulceration; and together with the occurrences, as mentioned above, allowed of a determination of the seat of the ulceration.

NEW FORMATION OF EPITHELIA IN CANCER.

Dr. C. Heitzmann also drew attention to the fact that epithelia were invariably surrounded and separated from each other by a narrow layer of the horny cement-substance, and that the rim of the cement-substance was always traversed by delicate cervical threads, the so-called thorns or prickles. He first pointed out in 1873, that these thorns were formations of living matter, which unite the reticulum of living matter of one epithelium with that of all its neighbors. Thus the living matter formed an uninterrupted layer throughout all epithelial formations, both in normal and morbid conditions. Dr. Louis Elsberg had found that in papilloma of the larynx, and that of the penis in many places, especially in the layer of cuboidal epithelia, the thorns became thickened, coalesced, and produced first solid roundish, oblong or spindle-shaped lumps of living matter, which afterward became transformed into a reticulum, and supplied with nuclei. These newly formed epithelia were wedged in between the old ones, which were pushed apart or exhibited corresponding bag-like excavations. Epithelia of cancer grew from connective tissue, as first asserted by R. Virchow, and five years ago corroborated by W. Hoeber, in H.'s laboratory. This mode of new formation he thought must be admitted against the views of Thiersch, Billroth, Waldeyer, and others, who claimed that epithelia of cancer could originate from former normal epithelia only. Besides, there were visible, especially in rapidly growing cancers, lumps of living matter in the cement-substance, exhibiting the whole series of changes toward the formation of new epithelia, exactly like papilloma. Two sources of epithelia, he claimed, should therefore be admitted: one was the connective tissue; the other the thorns or prickles in the cement-substance, which thorns thus were claimed to be formations of living matter.

Dr. Heinemann did not understand how some forms of bladder epithelia could be distinguished from those found in the cervix uteri.

Dr. Heitzmann replied that the double caudate epithelial, such as was found in the cervix, did not occur in the bladder.

Dr. Heinemann could not distinguish the double caudate epithelial, described by Dr. Heitzmann as belonging to the cervix, from those found in the bladder.

Dr. Peabody remarked that all the different varieties of epithelia were found in the bladder; in fact, he was accustomed to use that organ for the purposes of demonstrating the different varieties to students. He confessed his inability to make any diagnosis from the epithelia alone.

Dr. Satterthwaite remarked that he believed specific statements made as to the precise locality from which epithelial corpuscles came, when occurring as urinary deposits, should be received with much caution. In the matter of making differential diagnoses as to the location of a disease from such corpuscles, it was doubtful if we had gained much of late years. He, personally, was inclined to be more conservative than when his attention was first directed to these matters, and he thought that most of his colleagues in microscopic work occupied the same position. In a general way we were reasonably sure of being able to make a diagnosis between the epithelium of the mouth, bladder, vagina, and tubes of the kidney. The former and latter were probably the most certainly detected—epithelia in the form of casts were perhaps absolutely unmistakable when occurring in urine. Beyond these limits there was great opportunity for error, and this arose from the most natural reasons. In the first place, the epithelium varies according to its position in the organ, then often as to its depth from the surface. Again, where the epithelium of one part is exchanged for a different variety, there is almost invariably a certain amount of transitional epithelium which in form and shape assumes all sorts of gradations between the two. Then, also, the corpuscles undergo peculiar changes, if inflammation happen to be present, or in passing through some physiological act, such as menstruation.

In this connection he wished to call attention to a point in urinary pathology that had some clinical importance. In Ebstein's article in "Ziemssen's Cyclopædia" he states that a diagnosis of pyelitis can be made with certainty when the characteristic epithelial cells of the renal pelves are found in purulent urine. These bodies he describes as flattened, laminated, caudate epithelial cells. Dr. P. L. Creedon, who looked into this matter in Dr. S.'s laboratory, somewhat over a year ago, found, both in the ureters and urethra, corpuscles corresponding to this same description, and after comparing drawings of those which he made with the camera, practical distinction seemed to be impossible. Dr. S. also stated that he had as yet failed to see that epithelial bodies were uniformly united to one another by the delicate processes called "prickles" just described. This condition, which had been recognized for many years in the Malpighian layer of the skin, he had often seen in papillomas and epitheliomas; he had not been able to see it in scirrhous and medullary carcinomas. He was not now prepared to state that "prickles" did not exist in other instances. It should be remembered, however, that in dealing with these topics most modern microscopes are unable to give us much aid, for many of the highest lenses give illusory appearances. He would say the same thing of the intra-cellular networks already alluded to and beautifully figured by Klein in his recent atlas. Dr. S. stated that he was still unable to convince himself that such a network existed in normal epithelial corpuscles. He had seen appearances of this nature under pathological or artificial conditions.

Reference to the illustrations in some of the best and most recent works on microscopical subjects would also show that these views have not yet obtained much sanction.

THE CAVITY OF THE TYMPANUM AND THE OSSICLES OF THE EAR.

Dr. Rudolf Tauszky presented two specimens representing the cavum tympani, the bony portion of the Eustachian tube, the cells of the mastoid process of the temporal bone with the moving apparatus of the ossicles of the middle ear, and also demonstrated the membrana tympani.

These preparations were presented to him as a *memento* by his former schoolmate, Prof. Adam Politzer.

He also showed the articulations existing between the head of the hammer and the anvil, and the longer or descending process of the latter with the stirrup, of the stirrup with the fenestra ovalis. Anchylosis of the hammer and anvil articulation—adhesion of the descending process of the anvil with the membrana tympani—so also adhesion of the stirrup with the border of the fenestra ovalis. Even dislocations between the anvil and the head of the stirrup were found, according to Hyrtl, by Tröltsch, in his post-mortem examinations of deaf persons, as causes of deafness.

NEW STAINING FLUIDS FOR MICROSCOPIC SECTIONS—METHYL-GREEN AND BISMARCK BROWN.

Dr. Satterthwaite presented, on behalf of Dr. W. H. Porter, a number of microscopic slides which exhibited the action of some new reagents that had come into use for histological work. He first exhibited a normal human kidney, injected in two colors, but which had subsequently been stained in Bismarck brown. The method was practically the same as that given by Weigert (*Archiv f. mikrosk. Anat.*, xv., p. 259). A concentrated aqueous solution is made by boiling and adding of the dye, gr. iij.. to distilled water, ℥j. The liquid is then filtered. Sections are immersed from half an hour to half a day. The longer period is found the most desirable. After removing from the bath they are placed for five minutes in a five per cent. solution of acetic acid. They then are passed through alcohol and oil of cloves, after the usual methods, and finally mounted in Dammar varnish. The color affects chiefly the epithelial elements which are clearly differentiated from the surrounding connective tissues. The borders of the corpuscles take a bright brownish-yellow, the nuclei an ochre brown. This coloring material appears to be the best we have at present for epithelium. It was observed that in the convoluted tubes of the kidney the striations of Heidenhain were unusually distinct.

A specimen of waxy liver was then exhibited. In this case the amyloid substance was beautifully differentiated by methyl-green. The color is at most precisely the same as that produced by the *violet de Paris* of Cornil. The merit of drawing attention to it seems to belong to Curschmann, of Hamburg (*Archiv f. path. Anat.*, lxxxix., 3., p. 556). A solution of about five grains to the ounce of water is used. The specimens are then bathed in the fluid over night. Acetic acid is not used to set the color, and the sections are immediately mounted in glycerine. The waxy portion assume a brilliant violet, the normal tissues a dull green.

A specimen of waxy liver prepared by the method of Cornil was also shown. This color, known as the *violet de Paris*, is also the methylaniline de Poirier, "350 N." The specimen had been prepared about a year and a half previously, and though it has passed through the regular method employed for mounting in Dammar varnish, the color was as bright as on the day of preparation.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, June 28, 1880.

Dr. A. E. M. Purdy, President, in the Chair.

The first paper of the evening was by Prof. J. C. Dalton, and was entitled

A READY METHOD OF MAKING BRAIN SECTION FOR POST-MORTEM EXAMINATIONS.

Dr. Dalton spoke of the imperfections in the present methods of making brain sections. They have this objection, that, after having opened the ventricles, if any lesion is found in the white or gray matter, it is difficult to tell exactly what its relations are. This is especially true if oblique sections are made. In order to prevent this difficulty, it is necessary, first, to have some contrivance which will hold the brain firmly and allow the knife to go in a certain plane every time. For this purpose Dr. Dalton had devised a kind of open box in which to hold the brain. An idea of its shape may be gained by taking a large cigar-box, removing both ends and the top, then cutting down the two sides at each end, leaving the highest part in the middle, which is connected by a bar of wood. Through this elevated middle portion of the two sides are vertical slits, and through these the knife is passed when the sections are made. The dimensions of the box are of much importance, as it should not be too large for the smaller-sized brains, nor too small for the large ones. The bottom is formed of a board 38 mm. thick, 357 mm. long, and 128 mm. wide. The sides are formed of pieces of wood 22 mm. thick, and are 140 mm. high. The slit for the knife is 2 mm. wide. In the centre of the wooden bar connecting the two sides is a hole. In this is placed the tube that leads from the lubricating fluid (glycerine and water). This lubricating fluid is turned on while the sections are being made. The whole contrivance is placed in a shallow pan. The knife used is a very long one, with a broad blade. Its dimensions are 46 cm. by 2½ cm.

When the sections are to be made, the brain is placed on its base, to the left of the vertical slits. It is then pushed along with the hand until the place where the first section is to be made is opposite the vertical slits.

The brain must slide easily, and, in order that it may do so, the bottom of the box is fitted with a plate of glass which is covered with the lubricating fluid. The knife must also be moistened with the same fluid, glycerine and water. After the brain is placed in position, it must be held firmly there. This can be done by laying a piece of raw cotton upon it and holding on with that. The first cut may be made just about the anterior edge of the corpus callosum. The brain is pushed along until this part is about opposite the slits. The lubricating fluid is then turned on, the knife drawn through the slits, and the section made with a single cut. It is most desirable to make all the sections of exactly the same thickness. The thinnest sections easily obtainable are 8 mm. In order to have them all of this thickness, a plate of glass is made which just fits the right half of the floor of the box. It is laid in loosely and can be raised up. After the first cut is made and the end of the brain removed, this glass plate is lifted up and placed directly against the cut surface of the brain.

The distance between the surface of the glass next the brain and the slit through which the knife passes is just 8 mm. The knife is then drawn through the brain again, and the first thin section is made. By tipping back the glass plate, the new section falls upon it and may be lifted away. It is then placed in a shallow dish and covered with water to preserve its freshness and keep open the ventricles. A number of sections were then made, which showed the various structures very perfectly.

One of the advantages of the method is that, knowing the width of the sections, the examiner can easily tell exactly where the lesion is, if any be found.

Another advantage is that there can easily be made tracings of whatever it is wished to record. The section is placed in a shallow dish containing glycerine and water. A piece of ground glass is then placed over the section, and with a pencil exact tracings can easily be made of both normal and morbid conditions. These tracings can be transferred to white paper, and these in turn very easily and cheaply photographed.

Dr. Dalton did not claim for this method that it gave absolute scientific accuracy, but for ordinary examinations it would be amply satisfactory.

The second paper of the evening was by **Dr. J. G. Kiernan**, entitled

THE PSYCHOSES OF THE SECONDARY FEVER OF SYPHILIS.

Dr. Kiernan said that he had not been able to find any literature upon this subject, and presented it now as something deserving study.

Four cases were related illustrating the disease. The first case was that of a man who, six weeks before admission to the asylum, had contracted the initial lesion of syphilis. On admission he had a fever (103°) and mental excitement with delusions. He was given quinine and sedatives, but they did little good. On the third day the syphilitic history was obtained. The patient was then put under mercurial treatment. His temperature at once sank and his mind became quieter. On the fifth day a roseola appeared on the skin. The mercurial treatment was then neglected by the nurse; the patient began to get wild again, and his fever returned. He had to be covered with cloths smeared with mercurial ointment, and put under restraint. He gradually improved, and in the course of a month was discharged cured.

Case II. was much like the first. The patient, twenty-five days before admission, contracted the initial lesion of syphilis. On admission he had mental excitement, was very talkative, and had a high fever (104°). He had delusions, and thought he saw ants, lions, wolves, etc. Quinine and sedatives had little effect. On the fourth day a roseola appeared on the skin. Mercurial treatment speedily relieved all the symptoms, and the patient was discharged cured.

Case III. was that of a man with criminal antecedents. On admission he had mental excitement and fever. His delusions were very marked. He had signs of a recent chancre on his penis. He was wrapped in a sheet smeared with mercurial ointment, when he immediately began to improve, his mental condition changing to that of quiet insanity and his fever disappearing. It was then learned that he had been discharged from a Massachusetts asylum, where he had been a quiet patient for years. He was taken to New York by some official and dropped in the streets with $2 in his pocket. He wandered into a dance-house, where he probably contracted the chancre found upon him. He subsequently continued in a condition of harmless insanity.

Case IV. was that of an old man, aged 75, who contracted the initial lesion of syphilis while a quiet patient in the insane asylum. Several weeks later he began to show much mental excitement. He had hallucinations and delusions, together with a high fever. The symptoms improved somewhat under mercury, but the patient became weak and eventually died.

From the study of these cases Dr. Kiernan drew the following conclusions:

1st. That the secondary fever of syphilis gives rise to certain psychoses.

2d. That it produces a species of *raptus melancholicus* allied to the delirium of alcohol, narcotics, and the essential fevers.

3d. That in pure cases no changes, either macro- or microscopical, are likely to be detected on post-mortem.

4th. That the fever of secondary syphilis has an allied action on the brain to the essential fevers, alcohol, and the narcotics.

5th. That heredity appears to exert a predisposing influence, age not seeming to have an effect, but that conclusions cannot be drawn decidedly on the latter point, from the paucity of observations.

6th. That the mercurial inunction treatment yields the best results, and is best applied in the excited state of the patient by his being wrapped in a sheet smeared with mercurial ointment.

7th. That asylum treatment is not advisable if it can be avoided.

Upon this latter point Dr. Kiernan said: "Examining carefully the facts that the superintendent in nearly all asylums leaves the medical treatment to his assistants while he contents himself with receiving visitors, assuming the duties of steward and matron, while the assistant physicians, burdened with the medical treatment, had, in addition, not unfrequently to look after the green-house, the patients' clothing, the patients' friends, and the admiring crowd of female relatives of the superintendent who visit the asylum; when we find two superintendents appointed for marrying trustees' daughters—one as a punishment for treating a criminal with influential friends too leniently when in charge of a penitentiary, another after having been relieved of a similar position because of his relations with corrupt paving contracts; when we find superintendents so ignorant of their patients as to notify the friends of living patients years in the asylum, that they are dead, it seems very safe to conclude that asylums are not hospitals. Since we find superintendents endorsing phrenology, and others finding the moral nature in the great sympathetic, while a third performs phrenological experiments in reproduction on his female patients, for which he is removed by one legislature and replaced by another, it is safe to conclude that superintendents are stewards chiefly remarkable for the presence of a medical diploma."

At the conclusion of Dr. Kiernan's paper,

Dr. Piffard gave an account of the action of the committee appointed to secure the passage of a bill regulating the practice of medicine in New York.

The Society then adjourned to the fourth Monday in September.

* * *

Salicylic Acid in Iritis.—Salicylic acid is gaining some repute in the treatment of iritis and iridocyclitis. It acts best in cases having a marked rheumatic character. It does not appear to be a very reliable remedy, however.

THE NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 13, 1880.

Dr. H. B. Sands, President, in the Chair.

ANEURISM OF THE INNOMINATE ARTERY.

Dr. L A. Stimson presented a patient with the following history: An Irishman, 34 years of age, presented himself at Bellevue Hospital about the 1st of January, 1880, for treatment for pain in the right shoulder, that had begun in the preceding March, had gradually increased in severity, and finally become so severe as to cause him to stop his work. Diagnosis of innominate aneurism was made. Treatment by simultaneous ligation of the common carotid and subclavian arteries was suggested, and the operation was performed on the 22d of January. The wound healed promptly and kindly, and no accident occurred in the course of the recovery. For two or three weeks the tumor remained unchanged externally; then it began to diminish in size, the murmur disappeared, and it solidified. Previous to the operation the lateral diameter of the tumor was three inches, and its height above the clavicle one and one-half inches. Its reduced diameter was about one inch, and its height above the clavicle half an inch. A distinct pulsation remained. Whether it was from within or was communicated, Dr. Stimson did not feel certain, and asked the opinion of the Society upon that point. There had been no recurrence of pain in the shoulder except once, two weeks after the operation, and it disappeared promptly after the application of a blister. In the progress of the case there was an extremely rapid pulse, reaching 115 to 120, without fever or pain to explain its occurrence. So far as he knew, it was the seventeenth complete case.

Dr. A. C. Post suggested that it was unusual to have after operation such a diminution in the volume of an aneurism with so much fluidity as still existed in the tumor.

Dr. Markoe thought that, by pressing his fingers into the neck by the side of the tumor, he recognized a distinct pulsation from the aneurismal cavity.

FRACTURE OF THE INTERNAL CONDYLE OF THE HUMERUS.

Dr. T. M. Markoe presented a patient who had received an injury of the elbow-joint, and the following was the history of the case: On the 11th of November, 1879, a young man 16 years old, fell, reached out his right arm to save himself, but in some way not well understood, he received the entire force of the injury upon his elbow. A dislocation backward was suspected, and it was reduced. About six weeks ago the patient was brought to Dr. Markoe by Dr. Field, of New Jersey, and at that time the elbow presented easily recognized features of fracture of the internal condyle. The result was union of the fragment with a restricted degree of motion.

DISLOCATION OF BOTH BONES OF THE FOREARM BACKWARD WITH FRACTURE OF THE OLECRANON.

Dr. Markoe presented a second patient, under treatment, who twelve days previously fell from a bicycle, striking upon both hands and forearms and the end of the right elbow struck the floor with great violence. Two hours after the injury, Dr. Markoe saw the patient, and found a dislocation of the elbow backward. Both bones of the forearm, retaining their relation the one to the other, were thrown backward and the olecranon process was broken. In consulting all the authorities accessible he had been unable to find any reference to the possibility of the occurrence of such an injury. It seemed more than probable that the same force which caused the dislocation became concentrated upon the olecranon process, and produced a fracture. Fortunately, the fibrous coverings were not separated, and the fragment was not withdrawn from its attachment to the shaft of the bone. At once it became an important question as to what position the limb should be placed in when dressed. When the limb was straightened he found a tendency to slipping forward; so much so, he feared, that if dislocation did not occur the forward displacement would be a serious matter with regard to the ultimate usefulness of the arm. On the other hand, when he bent the forearm upon the arm he feared a too great separation of the fragment of the olecranon; for, if the fragment had been separated and carried up as much as an inch by the action of the triceps, the question of treatment would have been a somewhat difficult one to answer. He therefore made a compromise, dressed the limb in the semi-flexed position, and the separation of the fragment was only very slight.

Dr. Briddon asked Dr. Markoe if he had seen the fragment of the olecranon drawn up to the distance of one inch.

Dr. Markoe replied that he had. The present case was the second of fracture of the olecranon *without* separation that he had seen, although he thought it occurred not infrequently. In the other case the patient recovered perfectly.

Dr. Sabine mentioned a case seen in Bellevue Hospital, in which there was fracture of the olecranon without separation of the fragment.

Dr. Post suggested that wide separation of the fragment was, in many cases, due to manipulation. In examining an injured elbow he always looked first for fracture of the olecranon, so as to avoid flexing the forearm if it chanced to be present.

The President remarked that the interest in Dr. Markoe's second case turned upon the mechanism of the injury, which did not seem to be explained. It had been taken for granted that two forces acted upon the limb; one upon the olecranon itself, and the other upon the hand, pushing the forearm backward and producing a dislocation. It occurred to him that possibly both lesions might have been produced by the action of a single force. It had been said that the olecranon process could be broken by hyperextension of the forearm, the olecranon process being violently driven into the olecranon fossa, and fractured near its middle part. If that was true, it was just possible that, in the case reported by Dr. Markoe, a fall upon the palmar surface of the hand may have produced hyperextension to such a degree as to cause the fracture.

Dr. Sabine remarked that the tip of the olecranon does not dip into the olecranon fossa so closely as to become a point of resistance to over-extension of the forearm. The lateral ligaments would be the parts first injured in such circumstances.

Dr. Markoe then read a paper

ON FRACTURE OF THE INTERNAL CONDYLE OF THE HUMERUS, EMBRACING THE WHOLE OR NEARLY THE WHOLE OF THE TROCHLEA.—(See p. 118.)

Dr. Briddon remarked that he had always adopted the method of resorting to passive motion long before union of the bone occurred, in all cases of fracture involving the elbow-joint, and it never appeared to interfere with union. All cases which he had seen had occurred in children, and he had begun passive motion at the tenth or twelfth day.

Dr. Markoe recognized the importance of Dr. Briddon's statement, and remarked that upon the question of passive motion, two views were entertained: First, that it should be begun early, and second, that it should be delayed until the parts were quite firmly united. He thought the safer plan was between the two. After the lapse of fourteen days, he usually recommended passive motion. He did not think it was wise to resort to it before the material which was to unite the fracture had been thrown out and begun to organize, although the result possibly might not be affected by an earlier adoption.

Dr. Geo. A. Peters remarked, concerning Dr. Markoe's posterior angular splint with a straight splint on the anterior aspect of the humerus, that, until his last case of fracture of the elbow-joint came under observation, he had used a posterior angular splint and an anterior angular splint, and had been well pleased with the results obtained. In his last case, which occurred more than a year ago—a case of fracture of the internal condyle—he put the limb in the position of strong flexion, and held it with plaster-of-Paris, and secured an exceedingly satisfactory result. The dressing gave the patient great comfort, and the control over the fragment was very perfect. He began passive motion as early as the twelfth or fourteenth day; made it frequently and faithfully, and the result was scarcely any perceptible deformity, and no loss of motion whatever. He favored early passive motion. In the case in which the plaster splint was used, it was bisected so that it could be removed and readjusted at any time without special inconvenience.

Dr. Mason remarked that he had used plaster-of-Paris in fracture of the external condyle, and it had given very satisfactory results.

Dr. Markoe thought that in a case of ordinary fracture of either the internal or the external condyle, without special tendency to displacement, the plaster-of-Paris splint might answer a very good purpose. He, however, should be unwilling to leave so delicate a displacement encased in a plaster-of-Paris splint for fourteen days, and preferred to employ an apparatus that enabled him to watch the exact condition of things, and gave him timely opportunity to correct whatever of displacement possibly might arise during the progress of the case. In ordinary cases, where there was no tendency to serious displacement, the plaster dressing doubtless was very good, but, in the class of cases under consideration, when it was the displacement that made the arm more or less useless, he preferred a dressing that enabled him to daily inspect the parts involved in the injury.

Dr. Keyes remarked that, in anchylosis following injuries about the elbow-joint, the child, as a rule, could not be trusted to make such passive motion as was necessary. He then referred to a case in which the joint became so stiffened in a boy twelve years of age, who would do nothing of his own accord toward restoring motion, that the case was nearly given up, when it was suggested that a row-boat be furnished him and he be allowed to spend as much time on the river as he wished. The result was that he worked his elbow-joint free in about two months without knowing why he should be allowed to indulge so freely in the recreation.

The Society then adjourned.

Correspondence.

“WHETHER VIVISECTION PAYS.”

To the Editor of The Medical Record.

Sir:—The editorial review of my article in *Scribner's* on vivisection, in the Medical Record of July 10, seems to have included me among “the laity who, without knowing much regarding the facts, have yet a good deal of sympathy with the appeals to their humanity made by anti-vivisectionists.” Permit me to correct this error by reference to the July number of *Proceedings of the Medical Society of the County of Kings* (Brooklyn, N. Y.), p. 196. As a member of the medical profession, I trust you will accord me space not only to indicate some inaccuracies in your criticism, but also to suggest that in the positions taken in my article, I have hardly displayed that lamentable ignorance which you infer. The question of unfairness in my treatment of the subject, or of mental obliquity in other directions, I am quite willing to leave to the candor of such professional men as may do me the honor to read my paper.

1. My critic affirms at the outset that, regarding vivisection, “the writer takes the ground that it does not pay, at least not very well.” This is a mistake. I distinctly affirmed that “to the practice of vivisection we are indebted for nearly all our present knowledge of physiology;” that, “as a means of teaching physiological facts, vivisection is unsurpassed;” and even that “*no* experiment, however atrocious and cruel, if performed to illustrate some scientific point, was ever without *any* beneficial result.” In no part of my paper did I take the ground that vivisection—*as a whole*—does not pay.

2. Referring to my description of experiments, which you admit are “annually performed in the medical colleges of this city,” you assert that “the *fact* that these experiments are *all* done under anæsthetics, is not brought out at all.” I do not understand this. When Prof. Flint states in his “Physiology,” in regard to the formation of a pancreatic fistula: “it is generally better *not* to employ an anæsthetic” (p. 270); that in one of Bernard's experiments, “it is not desirable to administer an anæsthetic” (p. 470); that “*we should avoid the administration of anæsthetics* in all accurate experiments on the glycogenic function;” that “*we have lately been in the habit, in class demonstrations, of dividing the fifth pair in the cranium without using an anæsthetic*,” upon what grounds does my critic allege of these same experiments that they are all done under anæsthesia—and charge me with “unfairness?” Is this scientific criticism?

3. Do I correctly understand the Record to allege that, with *one* exception, *all* class demonstrations at Twenty-third Street are at present performed upon animals in a state of complete anæsthesia from ether or chloroform? Is curare or woorara never used to avoid the “exhibition of pain,” or regarded there as an anæsthetic? Are no animals poisoned to show the action of drugs—as by strychnia, for instance—a demonstration pronounced by Dr. Taylor (44 years Lecturer on Toxicology at “Guy's”) as “unjustifiable” and “a purposeless cruelty?” And if this uniform painless experimentation be the rule at Twenty-third Street, is it also alleged of the other medical colleges in New York? The experience of recent graduates hardly confirms what the Record appears to allege.

4. Of my citation from various authorities you remark: "The quotations are brief, and some of them from documents nearly ten years old." In my article thirty-nine references or quotations were made to statements by various scientific and medical authorities. *Two* of these were from Dr. Elliotson's "Physiology"—the testimony of an eye-witness to the cruelty of Magendie and Brachet. *One* other was dated 1872. Of the remaining thirty six, none are from documents of earlier date than 1876. Whether these quotations or references were "to the point" I leave to the reader.

As a physician I decidedly object to being classed among that extreme school of humanitarians who patronize the shambles and advocate the abolition of vivisection. On the other hand, I believe that the opposition to it will never cease until some such system of State supervision exists in this country as obtains in England. My paper was an attempt, from this standpoint, to indicate a "via media" in vivisection which should satisfy both humanity and science. If, in this endeavor to state the limitations of justifiable experimentation, I have done injury to the legitimate demands of scientific inquiry, no one will more readily acknowledge the error than myself. Are the positions taken in my article supported by reliable scientific testimony and opinion? Permit me to restate them:

I. "*The highest scientific and medical opinion is against the repetition of painful experiments for class teaching.*" In support of this, I gave the opinions of Sir Thomas Watson, Sir James Paget, Sir George Burroughs (President of the Royal College of Physicians), Prof. Huxley, and Prof. Darwin. I might have added that of Prof. Rutherford (to whose experiments you refer): "I do not think it at all necessary that any higher animal, *such as a dog or a rabbit*, should be subjected to pain for the education of medical students;" or that of Dr. Sharpey, professor of physiology for thirty years in a London medical school: "Such experiments as those of Magendie on the nerves *ought not to be repeated*." This is my ground; is it that of the Medical Record, and of the physiologists of this country whose views it advocates?

II. "Habitual familiarity with the infliction of pain upon animals has a decided tendency to engender a sort of careless indifference regarding suffering." Is this seriously denied? Can it be necessary to bring forward, in addition to the evidence adduced regarding Magendie, the opinions of Sir James Paget, of Sir George Burroughs, of Drs. Sibson, Sharpey, and Anthony—men who studied in Paris forty years ago? Must we detail the experiments of Mantegazza, of Spalanzani, of Paul Bert, of Brachet, of Bouillard, of Brunner, of Wertheim, and of others, in proof of this proposition? You tell me that my position is "absurd." It is, then, an absurdity shared by physiologists and physicians who are quite able to judge. Dr. Abernethy, in his physiological lectures, said: "I know these experiments tend to harden the feelings." Dr. Rolleston, Oxford Professor of Physiology, declared that he would consider the exhibition of pain in a lecture-room demoralizing to pupils, that the "sight of a living, bleeding, quivering organism *most undoubtedly does* act on that lower emotiono-motor nature which we possess in common with carnivora." "Watch the students at a vivisection," says Dr. Bigelow, of Harvard University. "It is the blood and suffering, not the science, that rivets their breathless attention. *Vivisection deadens their humanity and begets indifference to it.*" These opinions may be "novel to the medical student;" does that make them absurd, and unworthy consideration?

III. In regard to the influence of vivisection over therapeutics, the Record has misapprehended my position. You admit, as in a measure true, that vivisection has furnished no specifics, and has only given us "a mass of questionable theories." I asserted nothing stronger. My thesis was, that "*during the last quarter of a century*," painful experimentation "*has not resulted in the discovery of a single remedy of acknowledged and generally accepted value in the cure of disease.*" Particular care was taken to acknowledge not only the value to therapeutics of physiological knowledge, but also the possibility of future benefit from vivisection. The proposition confined to the experience of the past twenty-five years is a very definite one. How is it confuted? My critic begins with the discoveries of Galen (A.D. 130-201); cites those of Ambrose Paré (about 1539); of Harvey (1619); of Aselli (1662); of Hunter, (1785); of Magendie, who died in 1855; and so, covering almost the entire Christian era, comes to our own time. Is this refutation? Did space permit, I should certainly challenge the inferences you suggest regarding the debt due to vivisection, even in the other cases mentioned in your summary. But I fail to see how they touch the one proposition I laid down. If my critic, omitting reference to past ages, will indicate which of the discoveries mentioned meets and disproves every particular of my proposition, adducing at the same time references to the original series of experiments, I will not only esteem it a favor, but will hasten to acknowledge my error.

It is no object of mine to ignore or belittle the true value of vivisection. But, on the other hand, the interests of science can never be truly advanced by extravagant and unsupported claims of utility or potency in its behalf. Above all others, our age is distinguished for its attachment to scientific truth. We may not always agree regarding the methods by which nature is to be interrogated; there can be no difference of opinion as to the value of truth itself.

Albert J. Leffingwell, M.D.

Dansville, N. Y., July 15, 1880.

[We are very happy to give Dr. Leffingwell a hearing upon the important subject of which he writes. We can assure him that we have every wish to give full credit to him for sincerity in his opinions, and we would add that our omission of his medical title was entirely unintentional. We do not doubt that Dr. Leffingwell is equally desirous with us for the advancement of medical science. We must emphatically reaffirm our opinion, however, that physiological experimentation should not be hampered by legal restrictions, and that Dr. Leffingwell gave an exaggerated view of the cruelty and inutility of vivisection. We must reassert also our previous statements that the amount of pain inflicted upon animals in class-demonstrations in this city is insignificantly small, and is limited to less than half a dozen experiments in all the colleges throughout the course. It should be added also that even in these cases the pain is of short duration; and the idea that it "brutalizes" the student is, we feel sure, an entirely erroneous one.

We do not hesitate to take the position that it is right for a few animals to suffer briefly once a year, in order to impress a physiological truth. As to the pains inflicted in the laboratory, they are not caused needlessly or unintelligently. Our physiologists are humane men, and there has been no good reason shown by Dr. Leffingwell why their science should be crippled by legal restrictions. These are the grounds we took in our editorial review, and we do not find anything in Dr. Leffingwell's criticisms which weakens the position. We have not space to answer these criticisms in detail. We should say, however, that the general impression given by the article in *Scribner's*, is, that vivisection does not pay very well; and this impression would be particularly strong with the laity, who could appreciate the extended testimony to the cruelty and uselessness of vivisection, much more than the brief and isolated assurances of its scientific value. As regards Dr. Leffingwell's citations of authorities against the practical value of vivisection, we can only repeat again that it is facts, not opinions, which are wanted on this point. It is a fact that vivisection gave us strychnine and chloral. To offer in rebuttal the selected opinions of certain eminent men, that vivisection never gave us anything, is no argument, except perhaps with the laity, to whom Dr. Leffingwell's article particularly appeals. In regard to the value of vivisection to therapeutics, we did not say that it had given us "only a mass of questionable theories," and the putting such opinion so directly into our mouths savors of a carelessness which we had, perhaps, a right to expect, but which is hardly the more excusable on that account. Dr. Leffingwell's proposition to the effect that painful experimentation in the past twenty-five years has furnished the profession with no popular remedy for disease, it seems to us, is neither ingenuous nor to the point. If the proposition were true, it would not follow that painful experimentation was of no therapeutical use. The question that it is desirable to settle, is, whether vivisection, painful or painless, has been, or is likely to be of practical therapeutical value. That it has been, and is to be of very great value is what we asserted, and what we believe was sufficiently proved in the editorial under discussion. It certainly is a fact that vivisection has in the past twenty-five years contributed important remedial agents and methods to medicine and surgery. Even a slight acquaintance with other documents than those furnished by antivivisection societies would have informed our esteemed correspondent in this regard.

We beg, in conclusion, to assure Dr. Leffingwell, again, of our full confidence in the honesty of his purpose. If we have spoken too emphatically on any point, it is because we feel so strongly that any law to regulate vivisection is uncalled for, and would prove here, as it has in England, an injury to the progress of physiological science.—Editor.]

ON THE RELATION OF FOOD TO LIFE.

To the Editor of The Medical Record.

Sir:—When Dr. Tanner announced his ability to fast forty days he was called a monomaniac; when he undertook to give a practical demonstration of his assertion he was denounced as a charlatan. Now, when there is no reason to think that he is an impostor or fool, his experiment is called barbarous, proving nothing and belonging to the class of exhibitions that should be suppressed by civil authorities. These are the only comments so far advanced by the medical profession on the subject of Dr. Tanner's "Starvation Exhibition." The last one strongly reminds us of Henry Bergh's argument against vivisection, and proves only that the subject is not properly understood by the party who expressed it. There is no doubt that the present experiment is honestly conducted, and that the period of fasting will exceed all expectations. That the present case is not a unique one is proved by a number of well authenticated cases in the past, but this does not remove the unnatural character of such a prolonged abstinence from food, which stands in an apparent contradiction to our current ideas of life. As there is nothing so provoking as to see the person persisting to live when condemned by the whole faculty to die, as is the case with Dr. Tanner, let us examine where the miscalculation was made, and what is to be learned by the present experiment and similar ones to come, as there is a fair prospect of a fasting boom. The main argument against the success of Dr. Tanner's strength is the same which is used to disprove the possibility of perpetual motion. To live means to consume. During fasting, consumption is carried on at the expense of the tissues, which can go on but a limited period of time, much shorter than that already covered by Tanner, when death results from exhaustion of the resources of life. This reasoning has a grain of truth, but essentially is a false one. Although life is intimately connected with the consumption of food, or of tissues in case of fasting, the mistake consists in assuming that life is the result of consumption, while in reality consumption is only the manifestation of life. If the former were the case how will we explain the fact that life ceases when the material of consumption is still abundant, as is always with animals that die from starvation. The generation of heat, development of secretions, repair of tissues call for a supply which is present in the form of blood, lymph, and tissues, but their quantity is far in excess of the amount that is to be consumed in the course of the time the animal lives when deprived of food. We must look for the cause of death from starvation in some direction other than the failure of materials to satisfy the above-named needs. It is sufficient only to notice that partaking of food has a stimulating effect; that the symptoms of starvation show themselves in so-called nervous disorders; that various means having the tendency to stimulate the nervous system make us less dependent upon food; that various individuals require different quantities of nourishment, the conditions of work, etc., being the same. All this would tend to indicate that death from starvation results primarily from the collapse of the nervous system, resulting from its deficient nutrition and stimulation, and not from the cause above mentioned. When food is withdrawn, the length of life will depend upon how long the nervous system can retain its vitality with the minimum of nutrition or stimulation. To properly understand this subject we have also to examine the relation of rest and work to the nervous tissue. Rest is just as necessary to life as food. If the amount of work is pushed beyond a certain limit the same result is produced as when food and rest are withdrawn, namely the function of the nervous system becomes altered or entirely suspended, and its structure breaks down. On the other hand, there exists an intimate co-relation of these three factors—food, rest, and work, as the amount of one determines the amounts of the other two. Is the extent of food and rest required, and of the work that can be accomplished, identical in every given case? Evidently not. As the result of every-day experience we have average quantities for each; but they belong to an ideal, average person which does not exist, and is only a mathematical conception. On both sides of these averages there exists most variable quantities. Recent pedestrian matches showed us how, in some cases, the amount of functional activity of the nervous system can greatly exceed the average level to which it can be pushed with safety. They showed also that the rest required by it can be unnaturally less than that compatible with the life of an average person. Mme. Anderson's exhibitions were exceedingly instructive in demonstrating the possibility of the nervous system not losing its vigor under the most unusual relation of rest to work. If then the nervous system can in some cases retain its vitality under the conditions of rest and work, so unnatural that they would prove fatal to an ordinary individual, why should we wonder if cases present themselves where the usual relation of nutrition and stimulation to the nervous system is similarly deviated from the standard? The latter is too closely allied to the former to doubt its possibility, and the object of Dr. Tanner is to prove it by actual experiment. We can explain such a tolerance to these different extraordinary conditions, by assuming that the functional activity of the nervous tissue of such individuals is followed by the results peculiar to it in a lesser degree than we are accustomed to see in every-day experience, permitting a wider range of activity which is followed by a lesser exhaustion and wear-out, consequently demanding less rest, stimulation, or structural restoration. It is to be regretted only that the profession did not avail itself of such a valuable opportunity to study a question entirely new, and which cannot be studied so well in the laboratory or at the bedside.

The Forty-Eighth Annual Meeting of the British Medical Association will be held at Cambridge on August 10th, 11th, 12th, and 13th, 1880. *President*, Denis C. O'Connor, C.B., M.D., Professor of Medicine in Queens College, Cork. *President-elect*, G. M. Humphrey, M.D., etc., Professor of Anatomy in the University of Cambridge.

The business of the meeting will be transacted in General Session and Eight Special Sections: on Medicine, Surgery, Obstetric Medicine, Public Medicine, Psychology, Physiology, Pathology, and Ophthalmology. There will be a Subsection on Otology.

There will be an Address in Medicine, by Dr. J. B. Bradbury; an Address in Surgery, by Mr. Timothy Holmes; and an Address in Physiology, by Dr. Michael Foster.

The following subjects have been arranged for discussion in the various sections:

1. *Medicine.*—On Hysterical Anæsthesia, opened by Dr. Bristowe; and on Asthma, introduced by Dr. Andrew Clark.

2. *Surgery.*—On the Treatment of Wounds, by Prof. Lister; and on Stricture of the Urethra, by Sir Henry Thompson.

3. *Obstetric Medicine.*—On Uterine Hæmostatics, by Dr. Atthill; and on the Removal of Uterine Tumors by Abdominal Section, by Mr. Spencer Wells.

4. *Public Medicine.*—On the General Working of the Public Health Administration in Great Britain and Ireland, opened by Dr. Alfred Carpenter and Dr. Francis T. Bond; and on Diseases communicable to Man from Diseased Animals when used as Food, by Mr. Francis T. Vacher and Mr. Edmund J. Lyon.

5. *Psychology.*—On the Influence of Alcohol on the Causation of Insanity.

6. *Physiology.*—Is Urea formed in the Liver? by Professor Gamgee; and on Sleep and Hypnotism, by Professor W. Preyer, of Jena.

7. *Pathology.*—The Influence of Injuries and Morbid Conditions of the Nervous System on Nutrition, by Mr. Jonathan Hutchinson; and on Micro-Organisms: their Relation to Disease, opened by Professor Lister.

8. *Ophthalmology.*—The Nature of Glaucoma: some Points relating to the Perception of Colors, by Professor Donders.

Subsection of Otology.—The Therapeutic Value of Electricity in Ear Diseases, and the Comparative Value of the Various Mechanical Aids to Hearing, with Special Regard to the Several Kinds of Artificial Drumheads, and to those Instruments which Assist Deafnesss, Conducting or Transmitting Sound, either directly or indirectly, to the Organs of Hearing.

The meeting opens in the afternoon with a short service and sermon by the Bishop of Ely. The Annual Address of the President is delivered in the evening. On the subsequent days, the general meetings will be held at 10 A.M., and the Sections at 2 P.M. The evenings are to be devoted to a soirée, a public dinner, and a conversazione. On the 14th there will be several excursions.

Dr. Tanner's Fast.—Dr. Tanner's watchers reported, on July 28th, that he had gone for thirty days without food. His condition during the last seven days has shown no remarkable change. His pulse, temperature, and respirations have continued normal. The dynamometer has registered from 77 to 88 kilogrammes. His personal appearance betrays no marks of suffering; his color is good, and his physical strength sufficient to enable him to walk a little. He has grown weaker, however, takes less exercise, and sleeps or dozes more. The quantity of water drunk and urine voided, with the decrease of weight, are here shown:

	Water drank. oz.	Urine voided.	Sp. gr. of Urine.	Weight.
July 20th........	15	19¾	1006	133½
" 21st..	29	20	1006–8	132½

" 26th........	21	22¼	1010–20	130
Total,	136	126⅝		

Since July 14th he has lost only two pounds.

Starling Medical College, Ohio.—The fees of the Starling Medical College remain for the present at the old figures, $45, instead of $75 as previously stated.

Original Lectures.

LACERATION OF THE CERVIX UTERI.

Twenty-fifth Lecture of the Course of 1880 at Rush Medical College, Chicago.

By R. STANSBURY SUTTON, A.M., M.D.,
PITTSBURG, PA.

(Stenographically reported for The Medical Record.)

Gentlemen:—In entering upon the discussion of lacerations of the cervix uteri, I stated that to Emmet was due the credit of having pointed out the importance of the injury, and of having devised the treatment for its repair. Based upon the correctness of his tables, we stated that nearly thirty-three per cent. of fruitful women, complaining of uterine disease, had laceration of the cervix uteri; that about one-third the labors followed by the discovery of this lesion, were tedious, but that rapid labor (whether it be spontaneous or produced by ergot) would also produce the injury. I cautioned you against the reprehensible practice of irritating the cervix during labor —by rubbing its surface with the finger, or pushing it back over the fœtal head, or of resorting to early rupture of the membranes to save time. I said this accident occurred with rich and poor alike, in the absence of an accoucheur, and in the hands of the most skilful; in cases with forceps and without; and that it was highly probable that laceration in first labors was the rule—spontaneous union of the tissues, in the majority of the cases, occurring during the lying-in period; and that lacerations occurred at the time of miscarriages and criminal abortions. I also called your attention to three points in reference to the subsequent menstruation of women who have unhealed lacerations of the cervix.

If recent, the flow will be "more profuse and irregular;" if the injury is old, and cystic degeneration and atrophy of cervical tissue have occurred, the flow will be "diminished in quantity and be as to time irregular." In cases where the injury is slight, no change in "quantity or time may occur."

Your attention was called to the fact, and the reason why lacerations occurring in the median line, either anterior or posterior, usually heal during the lying-in period; and also in our lectures on vesico-vaginal fistula, to the fact that anterior laceration of the cervix, which is most likely to occur in women with "pendulous abdomens and anterior obliquity of the uterus," might be followed by urinary fistula, when the laceration has extended through the septum and into the bladder. Your attention was also directed to an intractable form of retroversion, due to adhesions, the result of posterior laceration in the median line; also to the importance of cellulitis, a constant result of deep lacerations. The indications of lacerations of the cervix at the time of their occurrence, or during the lying-in period, were also fully discussed.

To-day we have to deal with the subsequent changes, the diagnosis, and the treatment of the injury. The forms of laceration in the median line, whether anterior or posterior, as a rule, heal up, leaving hardly a trace of their former existence. When the laceration is unilateral, as is often the case, it is usually upon the left side, and marks the position of the occiput at the time of the labor. The laceration may be and frequently is bilateral, splitting the cervix from left to right, and extending from the os externus to a point above the vaginal attachment.

Another form is that in which a number of fissures have occurred, and where the healing has not been complete. It is styled by Emmet the stellate variety of the injury. Instead of many fissures, you may have three: two fissures upon one side, and one upon the opposite side. When a laceration of the cervix, bilateral in character, or unilateral either, has gone below the vaginal attachment, nature, unaided, will rarely if ever entirely repair the injury.

In the event of a deep bilateral laceration occurring in labor, what are the changes which take place in the condition of the uterus? Let us trace them. Immediately after the laceration, the lips of the wound spread apart, and the attachment of the vagina slides up on the lateral walls of the cervix; considerable of the support of the vagina to the uterus is destroyed.

When the woman gets upon her feet the uterus is yet heavy; it drops out of its proper plane, descending in the vagina; its axis no longer corresponds to the axis of the superior strait, but deviates toward that of the inferior strait. The split cervix, still soft, becomes flattened out against the posterior vaginal wall, while the posterior lip of the cervix is being crowded into the cul-de-sac of the vagina. and the anterior lip is projected forward toward the ostium vagina.

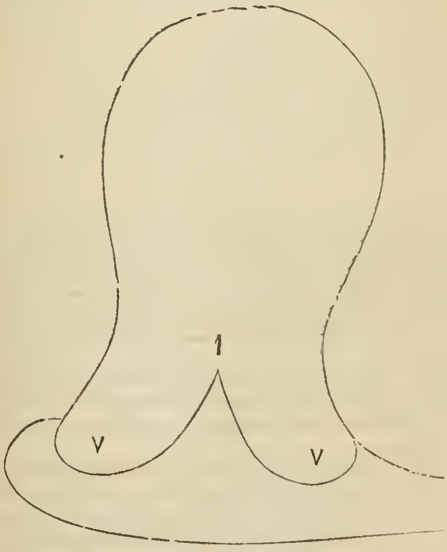

Fig. 1.—V and V represent the margins of a recently lacerated cervix. V, the posterior lip, is crowding backward into the posterior cul-de-sac; V, the anterior lip, forward in the axis of the vagina. 1 represents the site of the temporary intra-cervical os at the bottom or angle of the laceration.

As the subinvoluted uterus descends more and more, its fundus drops backward under the promontory of the sacrum, and we have a retroversion. Its axis now corresponds with that of the outlet of the vagina. If the perineum be lacerated, and its support destroyed, the yet subinvoluted vaginal walls will begin to drop, and, being followed by the heavy uterus, a complete procidentia may result.

This extreme result of the coincidence of these lacerations happily is not frequent. With the change in position, and the impingement of the split cervix on the posterior vaginal wall, the glands of the cervical canal, now exposed to friction, become irritated; they fill up, full of their peculiar secretion, and, bursting, bathe the cervix with a tenacious mucoid and albumenoid secretion. As this swelling progresses, the irritation extends to the submucous tissue of the cervix, which rapidly becomes swollen, and fold after fold of it is rolled out of the cervix, dragging lower and after them tissues from higher points in the cervical canal. Thus fold after fold of the lining membrane is brought forward, until the intra-cervical os now occupies a position about coincident with the original position of the external os. See this diagram. The curved lines represent the advancing folds of everted tissue, and their union in the median line designates the changes in position of the intra-cervical os.

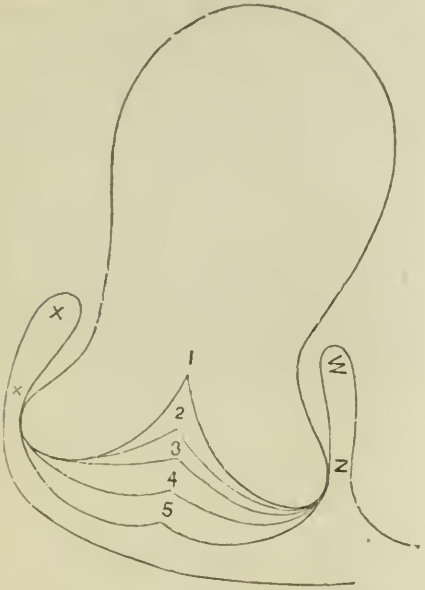

FIG. 2.—This figure represents the false cervix composed of reflected vaginal tissue and outrolled or everted intra-uterine tissue; this outrolling has taken place, as represented by the curved lines forming the angles 1, 2, 3, 4, and 5. These lines indicate the gradual process of eversion. The intra cervical os, point 1, has been rolled out to point 5, where it appears to be the external os; the vaginal attachment, X and Z, now appears by a reduplication to be at points X and Z, so that the cervix appears longer and larger than it actually is.

As the secretion rolls over this surface and irritates it; as the os now becomes so large that the tissues posterior to it become a constricting band, the cervix is kept in a constant state of violent congestion.

All these agencies unite to produce a rapid shedding of the epithelial covering, and finally leave the cervix in a state of erosion. The nerve-filaments which supply the part are also left exposed, and become the source of an irritation which is reflected through the nerve-centres and to various parts of the body, and the patient begins to experience grave nervous disturbance.

Supposing that the uterus has not descended to any great extent, the fact that a laceration exists, does, in many cases, become the cause of sterility. The mucus which plugs up the cervical canal acts as a mechanical barrier to the spermatozoa, and, as Goodell says, the surface, denuded of epithelium, is to the advance of the spermatozoa like a desert to the advance of an army. Irritating discharges from the vagina also pour out in immense quantity and kill the spermatozoa. Occasionally, however, a woman having received a laceration of this kind will go on bearing children for a time. Cervical atrophy is another of the results of the injury. As these glands fill up and burst, the sacs contract. You will feel the remains of these contracted sacs like shot situated under the tissues of the cervix. Owing first to the pressure upon the cervix which the distended glands produce, then owing to the subsequent contraction of the glands themselves, you have atrophy of the cervix, so that the anterior lip, most liable to be thus affected, may be found almost entirely gone.

In a deep bilateral laceration from the subsequent erosion you have more or less bleeding. The menses have become irregular, the woman may bleed profusely, often bleeding prior to her regular time. Her blood is being reduced in this way, and also through the immense amount of cervical discharge which is present. Her digestion is interfered with by the reflex nervous influence, and she will gradually approach a condition of "profound anæmia." If she be by heredity inclined to phthisis, now is the time when it will develop itself. These are some of the unfortunate results of lacerated cervix. There is another grave result. The erosion becomes a nidus for a form of disease fatal in character, and which comes uninvited by heredity. I refer now to epithelioma. In an old and large erosion, when the patient is approaching the climacteric period of life, epithelioma is very apt to develop.

This erosion of a lacerated cervix was what the profession throughout the world treated for ulceration of the uterus before the time of Emmet's discovery. The changes which occur in bilateral lacerations occur also to some extent in unilateral lacerations. If you will let this plate from Emmet's book, Fig. 81, p. 463, represent a unilateral laceration, we will trace the difference in change which takes place after it has occurred. As I told you before, when the laceration extends beyond the vaginal attachment, whether it be a unilateral or a bilateral laceration, cellulitis will occur. If it is unilateral, the cellulitis will be located upon the corresponding side between the folds of the broad ligament. As the broad ligament shortens as a result of the inflammation, the fundus of the uterus is drawn out of the median line toward the diseased side. As the intracervical tissues bulge out between the lips of the laceration against the lateral wall of the vagina, the cervix is pushed to the sound side; thus obliquity of the uterus is established. But the vaginal attachment has, you will observe by the diagram, slid up, so that now, when you look into the vagina, you would suppose that there was the same length of cervix upon the sound as upon the unsound side. When but one side is torn open, you have the rim of the circle of the cervix broken down at that point, and, as Emmet has said, it is much like knocking off the third leg of a stool. There is a tendency to drop down on the wall of the vagina, and thus increase the existing obliquity of the uterus. Now nature always makes an effort to heal these lacerations. In the cleft of a unilateral, as well as in the cleft of a bilateral laceration, granulations are thrown out; as they contract, cicatricial tissue is formed; and thus in every case of laceration you will find in the cleft a plug of cicatricial tissue. This plug acts just like a neuroma, producing an irritation which is spent upon the spinal cord and brain; and thus you have an explanation for the great nervous disturbances which often occur in these cases. How are you to diagnose a case of lacerated cervix? The patient complains of a series of symptoms which I will denote rational symptoms: she has depreciated health;

she has great nervous disturbance; she has backache; she has dragging sensations; she has an irritated bladder; she has probably some rectal disturbance; a line of symptoms which will warrant a physical exploration. Placing the patient upon the back in the lithotomy position, you will pass the index finger of the left hand up to the cervix. You will have the evidence there of a cleft, unilateral or bilateral; you will have the evidence of a large amount of discharge from the cervical canal; you will have the evidence of an enlarged cervix. If you will now place the right hand above the pubic symphisis, and over the fundus of the uterus, you will be able to determine that the cervix is larger than the body of the uterus, whereas, in simple hypertrophy, the body and the neck are usually developed symmetrically. In this case the cervix is flattened; it is spread out; it is larger than the fundus or body. You will now introduce the speculum. What sort of a speculum should you use? If you introduce a cylindrical speculum, you will not be able to discover anything except the probable discharge and erosion. If you use a bivalve speculum, you may probably be able to make a diagnosis through it; but it is better to use a Sims speculum, putting the patient upon her side; then with a pair of small tenacula, reach first for the posterior lip, then for the anterior; drawing them together, try to approximate them. If you are successful, you will see the cervix, which has been large, approach its proper size, and the fissure across its face will be seen. Your diagnosis is now complete in a case of bilateral laceration. Suppose, however, that you have a unilateral laceration to deal with.

You have detected the rent with your finger in the vagina. But through the speculum the two sides of the cervix are apparently of the same length, a condition already explained by the diagram. How are you to positively determine the vaginal attachment? Put your patient in the knee-elbow or knee-chest position. As the perineum is elevated, the air rushes into the vagina, the uterus recedes, thus disclosing the attachment of the vagina. You will also see the fissure extending down to the vaginal attachment, or possibly extending out upon the vaginal wall. This procedure, taught by Emmet, will also enable you always to determine whether you have a case of elongation of the cervix uteri.

Suppose, then, that you have completed the diagnosis, what will be the treatment preparatory to the repair of the injury? If the cellulitis which originally existed still remains in latent form—a condition evidenced by tenderness upon pressure made with the finger in various directions, and sometimes evidenced by the presence of nodules of lymph in the cellular tissue, which can be felt through the vaginal walls—if such a condition exists this must demand your first attention, for if you perform the operation prior to the removal of all this condition you will wake up the original inflammation. The uterus has fallen down, it is heavy, it is dragging, its very position is an interference to its circulation. So you must elevate the uterus, elevate it upon a proper pessary, carrying it up to the normal line, up to that point where the patient no longer complains of backache. If she cannot wear a pessary, you may support the uterus with proper cylinders of cotton, placing one in the cul-de-sac above the cervix and the other below the cervix, having first anteverted the uterus with your finger, and having medicated the cotton, you may, by doing this from day to day, coax her along until she can wear a pessary, when you must feel for the tender points, and, with reference to these points, alter your pessary in such a way that it will not bear upon them. The next thing is to insure perfect cleanliness, and also to relieve the vessels which now engorge and constrict the cervix. To accomplish this your best reliance will be the vaginal douche of hot water. Use large vaginal douches two or three times in the twenty-four hours, putting the patient upon her back and her hips upon a bed-pan. To relieve further this condition of the cervix, puncture the glands with a small tenotomy blade, making a little stab over the surface under which they lie, and then, with the dull wire curette, or a hair-pin held in the dressing-forceps, press out their contents. Having thus emptied the vessels and distended glands, your attention will be directed to the healing of the erosion. Paint its surface once every four or five days with Churchill's tincture of iodine, and in the meantime dress the cervix with glycerole of cotton or tannin, or with an astringent such as powdered alum or powdered persulphate of iron. You will gradually contract and limit the area which it covers. It may be that this erosion holds on, and, in spite of your best efforts, will not be healed. Then you may resort to the trick which Emmet notes in his book—that of drawing together the lips of the laceration, and uniting them temporarily, thus saving the surface from friction. You will go on with these remedies, at the same time giving your patient tonics, regulating her bowels, having her get a moderate amount of rest in a recumbent position, until your case is ready for operation. How shall you operate? You will need instruments and assistants. The night before the operation your woman should have had a purgative. In the morning, an hour before the operation, she should have a copious hot douche, in order to drive the blood out of the cervix as thoroughly as possible. You may place her in one of two positions: either that of Sims, or in an exaggerated lithotomy position—that of Simon. She should be etherized in bed before being placed upon the table. You will require some one to administer the ether, a nurse to hold the speculum, another to assist you, and an extra person to take care of the sponges. An additional assistant is never in the way should he be convenient. It is true that there are many of these cases which you can operate on without ether, but, as a rule, you will find it an advantage, and in all your early operations you will find it a decided advantage to have your patient under the influence of an anæsthetic. The instruments which you will require are these: a Sims speculum, with a wide blade; a pair of small tenacula, with long handles; two pairs of scissors, one with a long curve and one with a short curve; a long-handled bistoury, with a small blade; a number of sponge holders and sponges; a small uterine tourniquet; a double tenaculum, such as this one of Emmet's, for steadying the cervix during the process of denudation.

A pair of needle-forceps such as this, a pair of twisters for twisting the sutures, a pair of rough wire scissors to cut the wire. Having placed your patient in the left lateral position, and having passed the speculum which is held by the nurse, your assistant will steady the cervix with the double tenaculum. Dragging the uterus should be avoided, as the operation, if possible, ought to be done with the uterus *in situ*. You will then take up a small tenaculum, and picking up the tissue carefully, denude, with the scissors, the surfaces to be brought together on either side to restore the cervical canal.

Then having denuded the surfaces alike, and removed the cicatricial tissue in the cleft, the central surface undenuded will represent the new cervical canal. There is the os: now when you bring the denuded surfaces over, one upon the other, they should correspond. Having the surfaces alike, you will take the needle, threaded with a double thread, and secured by a half knot, catch it in front of the eye a short distance, seizing the lip of the cervix with a tenaculum to steady it, and to make counter-pressure you pass the needle through the lip, picking up all the breadth of the nude surface, the needle coming out upon the denuded surface just at the edge of the cervical tissue. Re-enter the needle and pass it through the opposite lip at the corresponding point; you will then attach the silver wire in this manner, and pull the silver wire into the line of the silk thread, and leave it there; you will then make a simple hitch of the silver wire upon itself in this manner, and passing down the loop toward the cervix, give the free end of the wire to the nurse, who will catch it under her hand as she holds the speculum; thus you will pass the stitches at short intervals, less than the eighth of an inch apart, until all the stitches are passed. Before you attempt to close the wound, wait for all oozing of blood to cease, or control it with hot water or alum water, applied with the sponges directly to the denuded surface. The oozing having ceased, or nearly so, you will now seize the hitch loop upon the suture in this manner, then with the wire scissors you will cut away the free wire close to the twister. You will now pass down the shield over the wire; as the shield comes down it approximates the lips of the wound, just as it brings together the arms of the wire suture; now you will begin to twist. Twist down in this manner, until you see that the turn has gone to the lower edge of the shield. If you twist below this point you will cut through or strangulate the tissues so that the sutures will cut out later. Having thus twisted the suture you will carry it over in this manner, at right angles with the tenaculum which replaces the shield.

Again place the heel of the tenaculum on the suture a half inch from the wound, and turn the suture, to which the twister is still attached, short across the tenaculum in that way. Now with a pair of wire scissors you will cut the suture just precisely in this angle, and it will lie smoothly upon the surface as you leave it. It will not turn up from the surface upon which you have placed it. In this manner you will introduce the stitches and twist them and leave them. Having twisted all the sutures and closed up the rent completely, the next point is to put the uterus in proper position; you will therefore antevert the uterus again with your finger. Your patient may now be put to bed.

You will have taken the precaution to have a number of hot bottles between the covers of the bed, in order that your patient may not run the risk of a chill; subdue the light of the room, and leave her with the nurse. In the event of vomiting following the operation, you can usually control it by giving small pieces of ice, or by small doses of lime water. When the effects of the ether have passed off, your patient should begin to take a light but nutritious diet, given in small quantities frequently repeated. The catheter may be required for forty-eight hours, after which time the patient will pass her urine over a bed pan, and after each relief of the bladder the nurse will throw a little warm water into the vagina to remove any drops of urine that may have trickled toward the cervix.

Original Communications.

EXTIRPATION OF KIDNEY.

Death on the Fourth Day After the Operation.

By FRED. LANGE, M.D.,
NEW YORK.

(The specimen was presented to the New York Surgical Society.)

This specimen belongs to a case, in which, after a long observation and due consideration of the symptoms, I felt warranted in performing nephrotomy. The patient died on the fourth day, without a drop of urine being discharged after the operation, and the *post-mortem* proved that those symptoms, which led me to conclude that the other kidney was healthy, induced me to perform an absolutely deadly operation. The case, therefore, despite its unfortunate course, is of great clinical value, besides its pathological interest, and may show that it is more difficult to state that the other kidney is intact, than to ascertain the disease of that organ which we are going to subject to our surgical procedure, the former point being, I think, of decidedly more importance than the latter. The history of the case is the following:

Mrs. K., 47 years of age, a native of Hungary, and from a healthy family, had enjoyed good health until three years ago. She went through seven normal confinements, the last of which was fourteen years ago. Her menses, since that time, have always been regular, though somewhat abundant. Three years ago, when walking on the street, she was attacked by a severe pain in her right lumbar region, so that she had to be carried home. Vomiting and nausea accompanied this attack, which was repeated twice on the same day. She was confined to her bed for four weeks, during which time, every one or two days, these attacks returned, sometimes with such intensity that she fainted. The trouble, by her physician, was taken for a climacteric one. She then enjoyed good health until the beginning of last year, when pain in her right lumbar region appeared again, together with trouble in urinating. This pain appeared in paroxysms, with vomiting and nausea in the beginning, of short duration, and daily or every other or third day. Gradually those paroxysms lasted longer, from two to three hours, and were often of labor-like character. Every slight concussion of the body was apt to produce this pain. The patient was obliged to walk slowly and carefully, and had often the feeling as if her right thigh might be drawn against the belly. She did not consult a physician until eight months ago. He thought her trouble to be caused by an enlarged uterus, and treated her accordingly, with some success, but without giving her entire relief.

In July, 1879, the patient was taken by a long and severe disease, attended with high fever, which continued several weeks, and there was almost perpetual intense pain in her right lumbar region, which occasionally became quite unendurable. She had to lay quiet on her back, because every motion or effort to assume a lateral position exaggerated her pain. There were again often-repeated attacks of vomiting, preceded mostly by a chill and followed by intense heat and perspiration. The patient lost flesh rapidly until about six weeks after the beginning of this disease, when a sudden relief occurred during one such attack of special intensity. She had the feeling as if something bursted in her right side. From that time the intense pain began to cease, her appetite returned, and her general condition improved. Moderate pain set in now and then, but at longer intervals, and gradually disappearing for weeks. The examination of the urine was made after that sudden relief, and a large amount of pus was found in it. I saw the patient in consultation with Dr. Bopp in October, 1879. She then had regained considerably in general health, had no fever, had a fair appetite and suffered no pain if she kept quiet. Every motion, however, caused an uneasy feeling in her right lumbar region, sometimes with pain toward the right thigh. Discharge of urine occurred without pain, and at normal intervals. Urine was of about normal quantity and color, moderately acid reaction immediately after being discharged, but very soon undergoing ammoniacal decomposition. It was uniformly turbid, and had an abundant sediment, mostly consisting of pus. There were also a few red blood-corpuscles, which, however, disappeared a short time afterward and never appeared again. There were numerous epithelia of the bladder, a few epithelia, probably belonging to the pelvis of the kidney, but very constantly numerous epithelia of the kidney, similar to white blood-corpuscles, but a little larger than these, presenting a distinct nucleus ; and finally cells still larger than these of epithelial type, but spherical. They had a sharp contour, presented a large and distinct nucleus. I did not find them every time when examining the urine. Sometimes they were found in groups, and I took them for epithelia of the tubuli recti in a state of soakage ; perhaps elements of a new growth. I never found concretions or crystals. After being filtrated the urine contained a slight trace of albumen. The specific weight was not taken.

The examination of the bladder showed no abnormity. The uterus was a little enlarged and somewhat prolapsed, its vaginal portion being hypertrophied and lacerated ; abdomen high, integument of the belly redundant and fat. In the right lumbar region, and in the space between the short ribs and the crest of the ilium, a deep-seated tumor could be detected by bimanual palpation. It seemed slightly movable, so as to allow a slight ballottement between the hands imposed in front and in the lumbar region. Its consistency seemed mostly resistant, and it remained doubtful whether a part of it, near the crest of the ilium, might not present fluctuation. The surface was irregular, with several flat, hilly prominences. The size of the whole mass, which extended toward the middle line in the depth of the abdominal cavity, was about that of the head of a new-born child. There was apparently no direct contact with the liver, while in front of the tumor the presence of intestines could be made out by percussion. The tumor was oblong ; its greatest diameter directed from the border of the sacro-lumbar muscle toward the umbilicus. It did not immediately touch the crest of the ilium, but was at the distance of about an inch from it. If the patient was lying half way on her left side, putting her right arm above the head, while a pillow was placed under the opposite lumbar region, the tumor caused the walls of the belly to protrude slightly, so as to make a flat prominence in the elongated line. No other abnormity could be detected on palpation or percussion, especially nothing which might have raised the suspicion that the left kidney might be affected. The former history also by no means justified that suspicion.

Regarding the diagnosis, there was no doubt that the tumor just described belonged to the right kidney. That the latter furnished the amount of pus contained in the urine. The slight mobility of the organ seemed to exclude the existence of an extensive perinephritic inflammation, while it pointed, together with the irregular, flat, hilly surface and the shape of the tumor resembling a kidney, to the assumption that the whole process was located within the tissue of the organ itself. In fact, the probability that we had to deal with pyonephrosis, was corroborated by the former history of the case as well as by the symptoms now in existence. The presence of stone seemed improbable as a cause of this process, since stones had never been found in the urine nor were they present in the bladder, though those colicky attacks mentioned pointed to a periodical obstruction of the urinary passage on the right side.

For the present, there being no urgent symptoms, and the patient being in a state of convalescence, I proposed to wait. I then observed the patient through the five following months, seeing her about every two or three weeks. She kept in bed almost constantly, since every exercise was apt to cause severe pain, and at intervals of two or one week one of those colicky attacks occurred. In the meantime there was often a feeling of intense burning in her right side, for which she liked the application of an ice-bag. Altogether the tumor within the next few months became decidedly smaller, the distance between it and the crest of the ilium growing larger. But during those attacks of severe pain it seemed again a little increased, the patient having the feeling of tension and the pain projecting into the right hip and thigh. The urine at those times contained decidedly less pus, but still a considerable amount of it. A partial obstruction at those times seemed therefore to exist. The quantity of urine or the quality of the sediment, as far as its microscopical elements are concerned, never showed any essential alteration.

From about the middle of February those attacks became more frequent, and about the middle of March the patient fell into a feverish state, had severe, persistent pain, extreme tenderness on pressure against the tumor, which seemed to her to be larger, and the first time, heretofore observed, the urine became quite clear, containing only a trifling quantity of sediment. Nothing was more probable than to assume that the ureter now was completely or almost completely obstructed, and that the urine was discharged from the other side. It was furthermore probable, that from the right kidney essentially but the sediments might be furnished, and that it might not have any importance for secretion of urine. because the urine secreted during this attack, like those before, presented the same quantity as in the free intervals, and finally it was probable that the kidney assumed to secrete the urine during this attack must be essentially healthy, because the urine did not present any considerable abnormity. The attack of pain just mentioned ended in a very typical and characteristic manner. First, somewhat more sediment appeared in the urine. The following day the patient felt a little relieved. Twenty-four hours later a considerable mass of pus was discharged and the patient felt again entirely relieved.

She now wanted something decisive done. She had been almost continually in bed during the last year, and I did not think that a spontaneous recovery was within the limits of probability.

I, therefore, proposed an exploratory incision, and in case I should find the organ diseased in such a way that its further presence might include danger to life, I had in view its removal, in the supposition that its condition was such as to allow extirpation. Otherwise, I proposed to open the organ supposed to be in a state of cystic degeneration, and to establish a fistula of the pelvis of the kidney. The operation was performed on the 24th of March. The patient was of short, stout figure, and the interval between last rib and crest of ilium was very narrow, and I did not choose the usual lumbar incision as recommended by Simon. An incision beginning from the edge of the sacro-lumbar muscle, and extending about eight inches in length, about one inch and one-half above the crest of the ilium in oblique direction toward the umbilicus, ending about on the edge of the rectus abdominis. The patient was lying on her left side, with a pillow placed under the lumbar region of that side. After the retroperitoneal space had been laid open I removed a part of the fat, pushed forward the peritoneum and intestines, and proceeded toward the capsule of the kidney. This was opened with the finger, and then a part of the renal substance appeared. Its surface was occupied by flat prominences, with pretty sharp ridges between them, but the tissue offered about normal resistance. I now tried to trace the hilus, and for that purpose I had to pass through a number of strong adhesions, which I loosened slowly and carefully. Immediately underneath it the kidney presented itself in a state of cystic degeneration. The pelvis was apparently not enlarged, nor could I distinguish any calculous matter by the touch. The whole organ seemed to have been somewhat displaced, its lower edge being too near the middle line, while the upper pole was directed outward; perhaps also it was situated altogether a little lower down than normal. The uppermost part I had not laid open yet, it being particularly fixed by adhesions. From that I concluded that it was especially diseased, and being under the impression that the other kidney was healthy, and that the right kidney was accessible to extirpation, though with difficulty, I decided to choose the radical way and to remove the organ. To incise the cystic part and to establish a fistula of the pelvis of the kidney I regarded as being too dangerous, on account of the deep seat of the cystic cavities near the vertebral column. It would have been impossible to secure free discharge of the purulent matter and urine from that spot, and to prevent it from infiltrating the retro-peritoneal tissue. On the other hand, it was rendered doubtful, whether the abnormities in the upper part of the organ, the latter being left, might not be apt to cause trouble by themselves. Finally, there was suggested by one of the colleagues present, that we probably had to deal with a new growth, and in assuming the possibility I hoped to give the patient the best chance at all events in removing the kidney, always being confident of the integrity of the other kidney. The former was slowly and carefully loosened from its environs, mostly by the fingers, here and there stronger adhesions had to be separated with scissors. Almost the whole hand had to be introduced into the wound, to reach the extreme edges of the kidney. Finally the pedicle was tied in four portions by double ligatures, and the organ removed. The wound was thoroughly washed with antiseptic fluid, drainage-tubes were introduced, no sutures applied, and a large antiseptic dressing concluded the operation, which had lasted about one hour and a half. The loss of blood was quite insignificant. The quadratus lumborum had to be cut across half way to allow a free outlet to the secretions.

The patient, after several hours of a collapsed appearance, presented a good condition, complaining merely of pain in her back and right hip. In the afternoon nausea and vomiting occurred several times. Pulse became full and strong, face flushed, slight perspiration all over the body. Not a drop of urine was found in the bladder until her death, which occurred on the fourth day, eighty-four hours after the operation. Temperature never exceeded 100.5° F. in ano. Her pulse on the second and part of the third day was abnormally full and strong, mostly 70 to 80 in number. After the third day patient became restless, a little soporous, without losing consciousness. The pulse became more frequent and weak, and finally she died rapidly in a state of coma, the face being congested until a short time before her death. Vomiting, which had been frequent within the first two days, gradually stopped, and only nausea remained. Respiration became deep and noisy. Believing that the case was one of simple anuria, I tried to stimulate perspiration, but the post-mortem on the fifth day after the operation proved that the removal of the kidney had deprived the patient of her only means of existence.

I lay before you both kidneys. The left one, which was removed by autopsy, consists of several cystic cavities, two of which contained a fluid-like urine; one of about the size of a hen's egg was filled with thick, cheesy matter. There is no trace of tissue of the kidney left. The pelvis of the kidney is entirely obliterated, and so is the ureter. Probably, for a number of years, no urine has been secreted from this organ. The disease which caused this degeneration might have occurred in the patient's earliest childhood, at least she could not remember having had any trouble in this side. The organ was at its normal place, and although cystic, it was only slightly increased in size, and its shape was not materially changed from the normal. The other kidney, the right one, which had been removed by operation, was about double the size of a normal one, and is now much smaller than at the time of the operation when it was filled with blood. It has been preserved in Wickersheimer solution, and shows pretty well its original coloring, but has become decidedly softer.

In a longitudinal section you see that it consists essentially of two parts: one, embracing about the upper two-thirds, is solid, presenting tissue of the kidney in a state of hypertrophy, measuring from two to three centimetres in height. The uppermost edge has a very irregular surface, and here the tissue is scattered with small knot-like infiltrations, measuring from several millimetres to one centimetre in size. A part of this tissue has been removed for microscopical examination. All those spots seem to be beginning abscesses. Some of them present a yellowish purulent appearance; others a more recent infiltration. The pelvis of the kidney, as far as it belongs to these upper two-thirds, presents a normal appearance. The lower third of the kidney is composed of a number of cysts, the largest having about the size of small hen's eggs. Those cysts contained urine and pus, and seemed not to have any connection with the pelvis. But a careful examination shows that there exist several narrow canals leading to the pelvis. You see one here. It seems to be covered with mucous membrane, and contains a number of small, irregular-shaped concretions. A large number of these concretions were present in the cysts themselves, the largest having about the size of a small pea. Evidently, those cystic cavities represent the substitute for the tissue of the kidney itself which has been destroyed by suppuration. The calices of the pelvis belonging to the pyramids affected in that manner are shrunken or obliterated, leaving here and there those narrow communications with the other part of the pelvis. The spot where the ureter starts from the pelvis is also abnormally narrowed, apparently by formation of a cicatrix, but it seemed to have been sufficiently wide to secure a perpetual outlet for the urine discharged, since its quantity never presented any considerable changes. The alterations in the upper part of the kidney may be due, I think, to the same process which has so far changed the lower third into a cystic one, but in an earlier stage.

I omitted, in making the diagnosis before the operation, to palpate for the other kidney through the rectum. The result of this examination might probably, have corroborated my opinion about this organ, since it was present at its normal place, and in about normal shape and size. I had it immediately under my finger at the moment of the autopsy, and still was not able to decide about its diseased state before I had removed it.

I am, however, sorry not to have tried the catheterism of the ureter. Post-mortem was allowed only with reference to the kidneys, and the bladder, therefore, was not seen; so I am unable to say whether or not the ureter was obliterated at its entrance into the bladder as it was in its uppermost part near the pelvis. In a future case I would not omit to try this means of diagnosis, though I think that some experience in its execution must be necessary to have it so sure as to make the whole surgical procedure dependent upon it.

In my case I think an exploratory lumbar incision on the left side would have been the safest way to make out the diagnosis as far as the kidney of that side was concerned.

Regarding the attacks of pain in the right side, there is, I think, no doubt that they were caused by retention of the purulent fluid within the cysts; perhaps in consequence of obstruction of their outlets by those small concretions. The latter I never found in the sediment of the urine.

◆

The Horrors of Vivisection.—The total number of vivisections in England and Wales, during the year 1879, was 270. Of these the number of experiments "in which," to use the language of the report, "there is reason to believe that some material suffering was caused," was about twenty-five. Of these twenty-five, fifteen were cases in which disease followed the inoculation of infectious matter, but in which no painful operation was performed; and ten were experiments upon as many frogs, in which an incision of the skin was required for the introduction of a medicinal substance.

To endeavor to abate the barbarities indicated above, a meeting of the International Association for the Total Suppression of Vivisection took place a short time ago. Earls, and knights, and marquises and like rubbish, who spend their summers running foxes out of breath and then shooting them, met and passed various resolutions for the furtherance of their cause. It is beautiful to think how much tenderness the sufferings of ten frogs can awaken.

THE LIGATION OF HEMORRHOIDAL TUMORS.

By WILLIAM BODENHAMER, A.M., M.D.,

NEW YORK.

The great antiquity of this operation, antedating as it does the birth of the Saviour of the world four hundred years, fills us with surprise, and claims our admiration in that it has come down to us with the experience of at least twenty-three centuries, with so little subsequent changes; and this fact alone is a sufficient plea for presenting its early history here. Among the multitudinous therapeutic measures which have been devised and adopted from time to time during this long period for the treatment of hemorrhoids, all of which have had their ups and downs in perpetual fluctuation of commendation and condemnation, ligation has stood the test of ages, and still maintains its superiority over all other methods for the removal of internal hemorrhoidal tumors, as being more simple, safe, rational, and effectual, and as having, at the present day, the recommendation, the advocacy, and the endorsement, with but few exceptions, of all the leading surgeons of Europe and America.

The use of the ligature as a therapeutic resource in the treatment of hemorrhoidal tumors I have dated back to the dawn of the Grecian era, or time of Hippocrates, the great physician of antiquity, who used it as one of his measures for removing such tumors. He directs that hemorrhoids should be transfixed by a needle and tied with a very thick woollen thread, for thus, says he, the cure will be the more certain. Whether the meaning of Hippocrates is that the needle traversing the tumor was to be armed with the ligature and the two halves of it tied separately, as is now sometimes the practice, or whether the needle was to be used unharmed, merely as a pin to transfix and hold the tumor in place, in order to facilitate its ligation, has given rise to some doubt. It seems, however, evident enough that Hippocrates in his description of the operation for trichiasis directs that in that operation the needle must be armed with the ligature, and then concludes by saying that hemorrhoids should be treated in like manner —that is, as must be inferred from his language, that the tumors should be transfixed by the needle armed with the ligature, as in the operation for trichiasis.* Galen particularly recommends the ligature in the treatment of hemorrhoidal tumors. After the tumor has been ligated as directed by Hippocrates, he advises that it be excised outside of the ligature.† Paulus Æginetae recommends the ligation of hemorrhoidal tumors. Previous to the operation he directs that the bowels should be evacuated by repeated clysters, in order to irritate the anus and render it disposed to eversion, and the rectum to protrusion. He then directs the patient to be placed upon his back, in a clear light, and a very thick thread to be passed round the lips of each hemorrhoidal tumor, leaving one as an outlet to the superfluous blood, for so Hippocrates directs.‡ Celsus advises the use of the ligature in certain cases. He says: if the head of the varix or hemorrhoid be small and have a slender base, it should be tied or ligated a little above the part where it is attached to the anus. When the hemorrhoid is very large, with a broad base, Celsus advises that it be taken hold of by one or two hooks and excised a little above the base; neither must any part of the head be left, nor any part of the anus be taken away. This may be accomplished by not drawing the hooks either too much or too little. When the excision has been made, a needle must be passed through the orifice of the vein or amputated varix, and below this a ligature must be applied.[*] Celsus doubtless has reference here to the entero-external hemorrhoids, those situated about the verge of the anus, partly within and partly without, and covered by muco-cutaneous tissues. His graphic directions for ligating and excising such tumors, and his precautionary advice in order to avoid unnecessary pains, subsequent cicatricial contractions of the anus, and hemorrhage, are most strikingly proper and judicious. Albucasis, in the treatment of hemorrhoidal tumors, preferred excision and burning; but if the patient objected, he then had recourse to ligation. The base of the tumors was to be transfixed by a needle armed with a ligature and securely tied.[†] Rhazes, the great Arabian physician of the tenth century, advocated the ligation of hemorrhoidal tumors.[‡] Haly Abbas, another great Arabian physician, approved of either the excision or the ligation of hemorrhoidal tumors, according to circumstances.[§]

I could here multiply the ancient authorities who employed and recommended the ligature for the removal of hemorrhoidal tumors, but deem it unnecessary. I will now cite a few authorities nearer our own time.

Heister always employed and recommended the ligature for the removal of hemorrhoidal tumors.[‖] Mr. Pott always preferred ligation to any other method of removing hemorrhoidal tumors.[¶] It is well known how decided Sir Astley Cooper was in his condemnation of excision, and in his advocacy of the safety and superiority of ligation, for the removal of hemorrhoidal tumors.[**] Mr. Howship says: "A strong circumstance in favor of the ligature I consider to be the following: by the ligature a certain degree of inflammation is sure to take place, with considerable tumefaction about the parts, and consequent effusion of lymph into the surrounding cellular texture. The tumors mortify, and the inflammation and swelling subside, but a permanent consolidation of structure is the result. The effused lymph is only partially reabsorbed, and the parts in which the disease naturally forms itself are thus rendered less liable to give way than they were originally. Where, on the contrary, the knife has been employed, scarcely any inflammation follows. The disturbance to the parts by excision is comparatively trifling, and the hemorrhage being always considerable, must, in proportion, diminish any tendency to inflame. The parts cannot, therefore, by this as by the other mode of operating, be left in a state of greater security than they were originally."[††] Sir Charles Bell says: "The operation for hemorrhoidal tumors by the scissors or the knife is incomplete unless the whole diseased parts are taken away, and the extremity of the rectum consolidated by inflammation. This intention is best fulfilled by the use of the ligature, which is the best method of exciting the necessary inflammation, and is the safest and least inconvenient of all known methods."[*] Sir Benjamin C. Brodie, when speaking of the ligation of hemorrhoidal tumors, says: "I conceive that it is not only one of the most effectual, but one of the safest operations in surgery."[†] The late and lamented Dr. Bushe of our city, preferred the ligation of hemorrhoidal tumors to any other method. He says: "I have now performed it, I am sure, upwards of a hundred times, and I have never seen a bad symptom follow it."[‡] Mr. Syme, on the ligation of hemorrhoids, says: "I feel warranted, after very extensive employment of the ligature, to state that it may be used without the slightest risk of any serious consequence. Indeed, in the whole course of my practice, I never met a case which either terminated fatally, or threatened to do so, when the ligature simply was employed."[§] Mr. Quain, with great success and satisfaction, always employed the ligature for the removal of hemorrhoidal tumors.[‖] Mr. Curling prefers ligating hemorrhoidal tumors. He says: "After a lengthened experience I can state that, with one exception, no fatal case of operation by ligature has occurred either in my private or in my public practice."[¶]

Inasmuch as the ligation of internal hemorrhoidal tumors is established upon as firm a basis as any other operation in surgery, I do not deem it necessary to present any additional evidence of this fact, besides that of the eminent authorities I have already given. I could, however, name as many equally distinguished surgeons in our own country, who are also just as strongly in favor of the same operation. So far as I myself am concerned, I can truly say that, having been in the constant practice for thirty-five years of removing hemorrhoidal tumors almost exclusively by the silk ligature, I have necessarily acquired some knowledge in relation to the operation. In my opinion, if it is judiciously performed, it is the mildest, safest, most certain, and most effectual of all known methods, and this, as I have already shown, is the settled conviction of the profession at large.

THE COMMON METHOD.

The prevailing method of ligating hemorroidal tumors is as follows: after the patient has completely evacuated the rectum by means of an aperient or relaxing enema, or by both, and has by straining efforts protruded the tumors as much as possible, each tumor is seized by either tenaculum or forceps and drawn down fully out of the anus, and close to the base of the tumor thus drawn down a stout ligature of silk, of gut, or hempen cord, is applied, and then the same drawn and tied with a double knot as tightly as can be; or a curved needle, armed with a double ligature, is passed through the base of each tumor, so as to divide it into two, and the cords tied as tightly as possible on each side. If the tumor or tumors are covered with skin, this is incised upon the circle which is to receive the ligature. When all the tumors are thus tied, they are returned within the anus, and an anodyne enema administered, and the patient required, in the meantime, to maintain the horizontal posture, to live on meagre diet, and to avoid having any fæcal evacuation for a few days. Sometimes, after ligating the tumors, especially if large, they are excised immediately outside of the ligature. This, in short, is the process usually practised at the present day in the ligation of hemorrhoidal tumors.

The greatest objection usually urged against the operation of ligating hemorrhoidal tumors, especially by those who consider all such as veritable varices, is the liability of the operation to produce phlebitis or pyæmia. This danger, in my opinion, however, has been, and still is, greatly exaggerated; of the fatal cases heretofore reported, the most of them were never verified by a *post-mortem* examination; consequently are deserving of but little confidence. Whilst the operation is attended with less danger than any other for the removal of hemorrhoids, still, it must be borne in mind that it is not entirely exempt from danger. Many also object to the usual operation, as now performed, on account of the severe pain which follows and continues for some considerable time, and thus hazarding tetanus, and to the confinement to bed or room for several days.

I believe, when phlebitis or pyæmia follows the operation, it is entirely referable to the previous and present bad state of the patient's general health, to his not having been at all a proper or a fit subject for it. When extreme pain follows the operation, causing great distress and suffering, and endangering tetanus, it is generally owing to the tumors having been in an irritable or inflamed condition when they were ligated, to the unsuitableness of the ligature, or the injudicious manner in which it had been placed upon the tumors. I have performed the operation in thousands of instances, and have yet to encounter the first serious accident.

In order, therefore, to guard against the dangers spoken of, the surgeon should never perform the operation without first making strict inquiry respecting the remote and the proximate causes of the hemorrhoids, and the previous and present condition of the patient's health otherwise. Should he find the patient suffering from organic disease of the lungs, the liver, the kidneys, the bladder, the uterus, etc.; or should he find the patient with a broken-down constitution from any cause, or in an anæmic or excitable state, or passing albuminous urine, he should hesitate to operate until the patient's condition was so improved, if possible, by proper treatment, as to justify it.

The danger is that, in some of the instances named, the blood, by being impaired or impoverished, by long disease, by miasmatic poisoning, by hemorrhages, or by any other cause, has lost its natural power of coagulation—hence pus or any other vitiated fluids find a much more ready admission into the circulation. It has been demonstrated that the coagulating power of the blood is the most efficient barrier, and the most effectual means, by which pus or any other foreign matter is prevented from entering into the circulation and producing inflammation of the veins, or blood-poisoning. A coagulum, as a general rule, will completely circumscribe purulent matter; indeed, under ordinary circumstances, such matter cannot circulate in blood-vessels, in consequence of its power of determining the coagulation of the first portions of the normal blood with which it comes in contact.

In consequence of several obvious objections which were continually being made against the common method of ligating hemorrhoids, I was led, a number of years ago, to carefully investigate the subject, with a view, if possible, to remove some of the objectionable features of it, or so to modify it as to make it less objectionable, without, at the same time, rendering it any less efficacious in the complete removal of the tumors. I first began by making some experiments upon both internal and external hemorrhoidal tumors when in a quiescent state, expressly with a view to ascertain whether any one point or portion of the tumor was more sensitive than any other, and more especially whether the mucous membrane, or other tissue from which such tumor proceeded, was more or less sensitive than the tumor itself or its covering. I found that the most sensitive part of the tumor was at its base, or at its immediate point of attachment; consequently I have ever since, in operating, been very careful so to adjust the ligature as not to tie it too close to the base, and that nothing but the tumor itself should be inclosed in its grasp. I also found that the lining membrane of the rectum, or other tissue to which the tumor is attached, is very much more sensitive than any part of the tumor itself. Now the question naturally arises, what is the cause of this difference in the sensibility of the natural textures from which the tumor proceeds and those of the tumor or foreign growth itself? The most rational inference which occurs to my mind at present is, that the former are more abundantly supplied with nerves and nervous influence than the latter. Be this as it may, however, the fact is as I have stated it, and it is in the power of any student to verify it. But on this, as on many other points of pathology and physiology, we are sometimes better acquainted with the *quo* than with the *quomodo;* in other words, we know the facts, but we cannot well explain them. My researches on this subject have plainly taught me that, so far as the natural tissues are concerned, the fine and delicate skin immediately without the anal orifice is the most sensitive; that the muco-cutaneous coat immediately within the anal orifice is next in point of sensibility, and that the mucous membrane of the rectum is the least sensitive of the three. I have, however, found the mucous membrane of the rectum much more sensitive than the mucous membrane covering the tumor. This must not be forgotten. Indeed, the foreign body and its covering, unless entirely external and covered with true skin, are much less sensitive than the three natural textures previously named.

THE IMPROVED METHOD.

I now propose to offer some improvement on the common method of ligating hemorrhoidal tumors, the success of which, in my hands, has been invariable, and warranted by an experience of many years.

According to the improved method of operating, the tumor to be ligated is never, as a general rule, seized by tenaculum nor forceps and pulled down; for if this is done a portion of the elastic mucous membrane of the rectum, to which the tumor adheres, also comes down with it, and is therefore almost certain to be included in the grasp of the ligature. Hence the additional pain, the protracted suffering, and the more or lesss ulceration which necessarily follow; for the operator cannot distinguish the true base of the tumor from any other part when drawn down in this manner, for all the parts generally have the same appearance. I always require my patients to extrude the tumors simply by defecating efforts, or by the efforts produced by means of an aperient or a relaxing enema. If one or all these means should fail to protrude the tumors, I employ a bivalve anal speculum, introducing and arranging it in such manner that the tumor which I design to ligate should fall between its blades; then, with suitable instruments, it can be ligated within the canal just as easily as if it were extruded or external. I scarcely ever ligate more than one tumor at one time, and I never employ a thick and stout silk or hempen cord with a hard twist in it, such as saddler's silk or the linen thread of the sewing-machine, which is almost as hard and stiff as silver wire; but I use fine soft silk ligature, well waxed, with scarcely any twist in it, somewhat like floss or dentist's silk. For, it may be observed, in proportion to the large size, the hardness and the stiffness of the ligature, will be the increased pain it will occasion, and the length of time it will take the tumor to slough off. As before observed, I am careful so to adjust the ligature as to exclude everything but the foreign body itself, and only make the ligature sufficiently tight to cut off the circulation—nothing more nor less. This fact can be known and adjudged by the appearance of the tumor whilst the ligature is being tightened. I am also very careful not to place the ligature very close to the base of the tumor, or place of its attachment, as this produces more pain and is not any more effectual in removing the whole of it. The small portion of the base of the tumor, below the grasp of the ligature, will sooner or later slough off or disappear by some other process, as I always witness. Indeed, the inflammation excited by the ligature in the contiguous parts is doubtless sufficient of itself to obliterate, by condensation of the surrounding cellular structure, any remaining portion of the tumor.

When the tumor is very large, or too large for one ligature, I divide it into two or more sections, according to its size, and multiply the ligatures, including but a small portion of the tumor in each. This is done by arming a suitably curved needle with a double ligature, passing it through the tumor a little above its base, and if necessary, repassing it, and tying each ligature separately, thus including in the stitches every part of the tumor, and underlaying it as it were, with a double uninterrupted suture. When any part of the tumor is covered with skin, or muco-cutaneous tissue, I usually incise this upon the same circle which is to receive the ligature afterward, by which more or less suffering is avoided. I sometimes, when the tumor is entirely external and covered with skin, and objection made to the knife or curved scissors, ligate subcutaneously, which causes it to shrivel and gradually to disappear. By this operation the integument, of course, is not interfered with, and much pain, suffering and inconvenience from the ligature otherwise applied, are avoided. The subcutaneous ligation of external hemorrhoids consists in encircling the base of the tumor with a ligature passed immediately beneath the skin. This is accomplished by the use of a proper needle, describing a considerable curve, and with it to puncture the tumor at a suitable place, and to carry a ligature subcutaneously half round the same. The needle is then to be brought out at this point, and re-introduced at the point of exit and carried round the other half to the original point of entrance, and then tied. If the tumor is large, it may be divided into two or more sections, as before described. This is the operation which is sometimes employed for the removal of nævi.

The Modus Operandi of the Ligature.—The ligature removes the tumor or foreign growth by two processes: first, by depriving it of its due supply of blood, and secondly, by making its way through the base of the tumor by ulcerative absorption. Now, while it is obvious that the first of these effects may be accomplished by the application of the finest and softest ligature, it is equally clear that the larger and harder the substance of the ligature is, the longer the time it will take, and the more extensive the inflammation, pain or irritation it will produce, in accomplishing the second. I repeat, then, that when a stout silk, hempen or linen cord is used as a ligature, which is comparatively a rough substance, especially when hard twisted, it will by its mechanical attrition, produce more inflammation and pain, and continue them longer than when the ligature is finer, softer, not much twisted, and not drawn too tightly. The ligature, however, must be drawn tight enough to interrupt all kind of circulation and physiological action in the tumor; if this is not accomplished the tumor may not perish, or perish very slowly, and more or less sensibility will remain in it. The desirable end, the complete destruction of the tumor, can be attained, however, without making the ligature as tight as it can be. The amount of strangulation should be just sufficient to arrest the passage of the fluids. The tumor, thus deprived of its vitality, first becomes blue or livid, and then softens, shrinks, and loses its volume, and acts in the same manner as any dead foreign body, which must necessarily come away through the eliminating powers of the system. When the entire physiological circulation of the tumor is suspended for twenty-four hours, the principal object of the operation is attained. After this the final result will be the same, whether the ligature remains on till the tumor drops, comes off accidentally, or is intentionally removed. When there is pain, after a certain period, the pain is not in the tumor itself, but in the contiguous natural textures not included in the grasp of the ligature.

Temporary ligation.—I sometimes employ temporary ligation—that is, suffering the ligature to remain upon the tumor for fifteen or thirty minutes only, and then removing it and replacing the tumor. This method, however, is only suitable in case the tumors are internal, and of a soft and spongy texture, similar to those to which the nitric acid is especially applicable. In examining the tumor a few days after the operation, it will be found to be smaller, and echymosis will be visible in all parts of it; and about the fifth or eighth day it will have entirely disappeared, with scarcely any pain or inconvenience during the whole process.

The proper time to operate.—The best time for the performance of the operation is when the tumors are in a quiescent state. I do not consider it good practice to operate when the tumors are very irritable and inflamed. I am in the habit, when such is the case, of waiting, if possible, until the irritability and inflammation have spontaneously subsided, or have been subdued by appropriate treatment. It often occurs that among several tumors which are in a quiescent state, there may be found one highly sensitive and irritable. This one can be easily distinguished from the rest by its florid appearance, or by its being tense, tender, and painful upon pressure. If the operation is performed when the tumors are irritable or inflamed, the pain and the general suffering will be greatly augmented. To subdue the sensibility, irritability, or inflammation of the tumors, I sometimes apply a solution of the nitrate of silver by means of a camel-hair pencil, and immediately after I apply olive or almond oil to the same. Two or three applications in as many days, are usually sufficient. The solution should be of such strength as not to produce a slough, not to abrade or to injure the surface. All that is required is the sedative power of the caustic, without its injurious effects. If applied of a certain strength, say from ten to fifteen grains of the crystals to one ounce of distilled rose-water, it will diminish the sensibility and irritability in a most remarkable manner. The patient, in the meantime, should live on bland and unirritating diet, and his bowels, if possible, should be relieved by enemata of the infusion of linseed, to which a little castor or olive oil should be added; or, by the use of the following aperient powder, one or two teaspoonfuls of which may be taken in a little water:

℞. Sulphuris loti,
Magnesia calcin.,
Saccholactin.............āā ℥ iv.
Misce et fiat pulvis.

When the tumors, however, are highly inflamed and swollen, as well as all the contiguous parts, to subdue the inflammation and swelling, I apply leeches, if not contra-indicated. They should, however, not be applied on the tumors themselves, but somewhere in the anal region, outside of the tumors. They are especially indicated when the tumors become strangulated, and difficult, if not impossible, at once to return. In such cases I have employed them with the most happy effect, and I am surprised that they are not more frequently employed. Indeed, when applied to the anal region, they are not only valuable in inflamed hemorrhoids, but as a revulsive remedy in many other diseases. It is in consequence of the large number of veins which accompany the arteries and expand around the rectum and anus, and contribute to the formation of the vena-portal system, that the margin of the anus was long since selected as the most proper and most eligible place where leeches produce their greatest effect, in chronic inflammatory affections of the liver, the colon, the rectum, and adjacent parts. Leeching the anal region, as a revulsive measure, was at one time, many years ago, so common in Great Britain that some of the poetic wits of that period immortalized the practice. Butler, in his celebrated satire, pleasantly alludes to this practice in one of the following lines:

"But with moon was more familiar
Than e'er was almanack well-willer;
Her secrets understood so clear,
That some believed he had been there;
Knew when she was in fittest mood
For cutting corns, or letting blood;
When for anointing scabs or itches,
Or to the bum applying leeches."*

Mr. Alexander Brome, the poetical wit and champion of the cavaliers of Charles the First, in one of his songs against the Rump Parliament, in allusion to Cromwell's hunting the members out of the house by military force, sings;

"Our Politique Doctors do us Teach,
That a Blood-sucking Red-coat's as good as a Leech,
To Relieve the Head. if applyed to the Breech.
Which nobody can deny."†

As true hemorrhoidal tumors vary in locality, structure, size, numbers, vascularity, sensibility, etc, so do they require modifications of treatment. Those in which, more than in any others, ligation is more especially indicated, are the internal ones which are florid, soft, and highly vascular, which protrude readily and bleed freely; also those internal ones which are indurated, dark, and with little sensibility, protruding at each evacuation, and attended with a free mucous discharge. Those round and sometimes blue tumors, located at the margin of the anus, and covered partly with mucous, and partly with muco-cutaneous tissue, should, when large, be ligated, after incising that part covered by the latter tissue. When any of these are very small, they may be let alone, but when any of these small ones are hard and painful, they should be punctured with a lancet, and their contents completely let out. Those tumors that are altogether external, or completely without the anus, and covered with skin, should be removed with the knife or curved scissors, or ligated subcutaneously.

I will here observe that the limits of this article will not permit me to draw a parallel between ligation on the one hand, and the several surgical measures now adopted for the removal of hemorrhoidal tumors on the other, such as excision by knife or scissors, écrasement, the actual cautery, the potential cautery; Dupuytren's combination of forceps, scissors, and actual cautery; the same modified by Mr. H. Smith, of London, of clamp and knife or scissors, and actual or potential cautery; M. Amussat's method of clamp and the caustic of Filhos; Houston's method of nitric acid; the galvano-caustic method of Middledorpff; the method of M. Richet of cauterizing the tumor in several sections by means of a peculiar forceps brought to a white heat; the method of forcible dilatation of the anal sphincters: all of which find advocates in able authorities. I must be pardoned, however, for making a few remarks on the method recently introduced, of injecting hemorrhoidal tumors with coagulent, hemostatic and cicatrisant solutions. From the great excitement lately manifested by a few fanatics concerning this method, some were inclined to raise the cry, *Eureka*, or led to believe that it, like Aaron's rod, was destined to swallow up all the other methods. It may be remarked, however, with regard to this new candidate for fame, that, as yet, it has no status in surgery, and it is questionable whether it ever will prove a real benefit to, or an advancement in that science, as it regards a safe and certain remedy in the treatment of hemorrhoids more especially. The profession, in general, are not yet sufficiently acquainted with its *modus operandi*, or in possesion of sufficient data, to pronounce a positive judgment, as to its merits or demerits; but I have no doubt all are quite willing to give it a fair field and wait for results.

I will now attempt to show how the injection of hemorrhoids was first thought of, and the manner in which it was most likely brought about. It is known that the morbid growths termed *nævi* have been treated by injection by some eminent surgeons for the last forty-five years, and it is also known that some hemorrhoidal tumors partake largely of the nævoid structure, or what Mr. John Bell called *aneurism by anastomosis*.* These circumstances, then, gradually and eventually led to the idea of injecting hemorrhoids also, the transition from the one to the other being so very natural and so very simple and easy, that it was, as it were, but a short or an imperceptible step to take.

* The Principles of Surgery. Vol. III., p. 283, London, 1826. In 8vo

The injection of nævoid growths was for the first time advocated and executed by Mr. Lloyd, as it appears in a very valuable paper entitled, "Observations on the Treatment of Vascular Nævi Materni," in the *London Medical Gazette* for October 1, 1836. Mr. Lloyd used a syringe fitted with tubes of different sizes. The point of the tube was introduced through the skin at a little distance from the growth and various fluids injected, such as nitric ether, nitric acid, in a solution of six drops of the acid to one drachm of water; solutions of the chloride of lime, sulphate or acetate of zinc, hydrochlorate of ammonia, aromatic spirit of ammonia, or iodide of potassium. A number of other substances were soon added to the list, and among them the perchloride of iron, after M. Malgaigne had introduced that preparation in surgical practice. It subsequently proved to be safer and more effectual as an injection in nævi than almost any other substance. M. Bérard injected nævi with nitric acid, as well as with the acid nitrate of mercury.* Mr. Tyrrell injected nævi with a strong solution of alum, first making a puncture with a lancet and then inserting an Anel's syringe.† If I mistake not, I have read the statement somewhere, that the late and lamented Professor Brainard, of Chicago, recommended the lactate, instead of the perchloride of iron as an injection in nævi, for the reason that the elements of the lactate are normal constituents of the blood.

Now it will be observed, that with but little variation, the same intentions or indications, the same kind of fluid substances, and the same kind of instruments which obtained forty-five years ago in the injection of nævi, now obtain in the injection of hemorrhoids.

So far as my reading extends on the subject, we are indebted to Mr. William Colles, Surgeon to St. Stephen's Hospital, Dublin, for first introducing the practice of injecting hemorrhoidal tumors. Mr. Colles, considering such tumors as vascular growths, resembling nævi in children, or erectile tissue in adults, conceived the idea of treating them by injection in the same manner we do nævi or erectile tissue. He put this conception into practice in a case in 1874, by injecting into the tumors the tincture of the chloride of iron, with the intention of exciting in them a certain amount of inflammation, and secure the coagulation of the blood in the minute vessels composing the growths, and their subsequent absorption. He says: "The hemorrhoids being protruded, I injected about twenty minims of the ordinary tincture of the chloride of iron into each hemorrhoidal tumor by means of a hypodermic syringe, which caused but little pain. Four weeks afterward the section was examined by means of a speculum, and no trace of the tumors could be discovered except three nodules of cuticle, each the size of a shrivelled currant." ‡

I was solely induced to present the subject here, of injecting morbid growths, including hemorrhoidal tumors, in consequence of the late and repeated reports, setting forth that a number of empirics in our country were employing the method of injecting hemorrhoids, and impudently setting up the fraudulent claim that they were the original inventors of this method, and that it owes its paternity exclusively to them. No quack, in my opinion, ever originated the idea of injecting hemorrhoids, or of inventing this practice; if there is such an one, I would like to see his name, and the record. All that these empirics have really done was merely to avail themselves of the numerous experiments and the practical information on this subject already extant, and to appropriate them to their own use. They have, therefore, done nothing whatever in this affair worthy of being commended, appropriated, or imitated.

I do not wish it to be understood that I am wholly opposed to the method of treating hemorrhoids by injection. Far from it, for it may, perhaps, hereafter be found valuable in certain cases; but for the present we have a long-tried, a much safer, a more certain, and a more effectual method in ligation. Five cases within the last two years have come under my own immediate care, in which the treatment by injection had been tried. All of them, in their results, were most unfavorable to the operation. One of them had an anal abscess and fistula to follow the first injection; another had an anal fissure and an abscess as the result of the injections; two had anal fissure of a very aggravated kind, doubtless caused by the escape of the carbolic acid through the orifice of the puncture; and in the fifth and last case, the first injection was followed by extensive sloughing of the cellular membrane in the vicinity of the tumor, and by a persistent hemorrhage. In each of these cases I subsequently removed the tumors by ligation.

In this country we are indebted to Professor J. H. Pooley, of Columbus, Ohio, for the report of three cases of hemorrhoids, which he successfully treated by the injection of carbolic acid.* We are also indebted to Professor E. Andrews, of Chicago, Illinois, for valuable services in collecting statistics relative to the injection of hemorrhoids. He obtained reports of upward of three thousand cases so treated by quacks generally, out of ten thousand cases treated in this country during the last nine years. He says the process of injecting hemorrhoids seemed to have been the invention of a travelling charlatan of Illinois, in 1871.† Drs. Pooley and Andrews have thus earned a strong claim to the thanks of the profession and the community for their useful efforts in endeavoring to take this practice out of the hands of the quacks, and of placing it before the profession upon a sound and scientific basis.

SIXTY-SIXTH ANNUAL REPORT OF THE MASSACHUSETTS GENERAL HOSPITAL, 1879.—This report shows that the average census of patients during the year was 163. The whole number of patients admitted during the year was 1,813. The number of out-patients was 18,960. The average cost per week for each patient was $10.54. The total annual expense was $89,295.57. The per cent. of deaths was 7.93.

The report of the *McLean Asylum for the Insane*, which is under the same management with that of the hospital, gives an average census of 157 patients. The admissions during the year were 76. The number discharged cured was 19; the per cent. being 25. During the year Dr. Edward Cowles took charge of the asylum *vice* Dr. Page, resigned. A home for convalescents has been planned, and the work on the building already begun. It is to be situated at Belmont.

QUININE SUBCUTANEOUSLY.

By J. CRESAP McCOY, M.D.,
HOUSE PHYSICIAN, BELLEVUE HOSPITAL, N. Y.

VARIOUS salts of quinine and other alkaloids of cinchona have been used hypodermically, the most common of these being in the form of Lente's solution, and latterly the hydrobromide of cinchonidia. All of these, however, have serious objections, viz., the amount of acid used in their preparation, and their low degree of solubility.

Having had bad results from the use of all these preparations, I finally tried "quinia bimuriatica carbamidata," the salt discovered by Drygin.

My observations have been, in the majority of cases, upon patients suffering from a disorder in which the reduction of temperature was desirable, or the specific action of quinine indicated. No attempt was made to obtain patients in good general condition; several were in the later stages of Bright's and phthisis.

Various quantities of the solution were used, and a record kept of the results in each case, which are as follows:

CASE I.—Urethral fever. Two injections, grs. x. each; no redness; after each, temperature fell 1° F.

CASE II.—Intermittent fever (convalescent). One injection, grs. v.; no redness.

CASE III.—Phthisis. One injection, grs. v.; no redness.

CASE IV.—Intermittent fever (convalescent). One injection, grs. v.; no redness.

CASE V.—Intermittent fever. One injection, grs. v.; no redness.

CASE VI.—Carcinoma of stomach; marked cachexia and anæmia. One injection, grs. v.; no redness.

CASE VII.—Phthisis; cavities; marked hectic. One injection, grs. v.; slight redness and tumefaction, disappearing in forty-eight hours.

CASE VIII.—Peritonitis. Very much emaciated. Been confined to bed four months; just recovering from acute general peritonitis, presenting the remains of several abscesses resulting from the use of Magendie; her general condition so bad that when these were opened they refused to close. Three injections, grs. x. each; slight redness after second.

CASE IX.—Pleuro-pneumonia. Temperature 105°. One injection, grs. x.; temperature fell 1° in three hours; no redness.

CASE X.—Empyema. Two injections, grs. v. each; no redness.

CASE XI.—Urethral fever. Three injections, grs. x. each; temperature, at time of giving, from 101° to 102°, falling to normal shortly after administering; no redness.

CASE XII.—Pleuro-pneumonia. One injection, grs. v.; no redness.

CASE XIII.—Pernicious fever (convalescing). Two injections, grs. x. each; no redness; no temperature taken. This case presents the remains of five abscesses following the use of grs. xl. quinine in the form of Lente's solution.

CASE XIV.—Remittent fever. Temperature on admission 106°. Five injections, grs. x. each, immediately. In six hours temperature had fallen to 101°; thoroughly cinchonized at this time; subsequently three injections of grs. xv. each, given at different intervals, none of which produced the slightest redness or tumefaction.

CASE XV.—Pernicious fever. Temperature 108°. Five injections, grs. x. each; temperature not controlled; no redness; death resulting in twenty-four hours.

CASE XVI.—Remittent fever. Temperature 104½°. Six injections, grs. v. each, given at intervals of an hour; cinchonized one hour after last. Six hours after last injection temperature 100°; did not again rise much above this; no redness or tumefaction.

CASE XVII.—Remittent fever, hepatic abscess, subacute pleurisy. Three injections, grs. x. each; slight tumefaction after second, which, however, cleared up readily.

CASE XVIII.—Intermittent fever. Four injections, first two containing grs. xx. each; second two grs. x. each; first was given in one spot without removing the needle, some force being found necessary to accomplish this; the second, given two hours after the first, in two spots, grs. x. each; patient cinchonized one hour after second injection, and remained so for twelve hours; temperature at time of administering, 101°, in six hours, normal; the last two injections were given during convalescence; no induration followed either of these injections, excepting the first, where the large amount was given in one place; this, however, disappeared in seventy-two hours without treatment.

CASE XIX.—Dysentery. Two injections, grs. x. each; no redness; temperature not observed.

CASE XX.—Phthisis; thrombosis veins of thigh. One injection, grs. v.; no redness.

CASE XXI.—Peritonitis. Two injections, grs. x. each; no redness or tumefaction.

CASE XXII.—Pott's disease; child six years old. One injection, grs. v.; no redness.

CASE XXIII.—Malarial anæmia. Two injections, grs. v. each; no redness.

CASE XXIV.—Intermittent fever. Five injections, grs. l. One injection of grs. x., given hourly, until grs. xl. had been given; thoroughly cinchonized after fourth injection. Temperature at time of administering, 102½°, falling to normal in six hours, never rising again; no redness or tumefaction followed either of these injections.

CASE XXV.—Pleurisy. Three injections, grs. v. each; no redness.

CASE XXVI.—Remittent fever. Seven injections, grs. xl., given at one time; cinchonized thoroughly in an hour and a half. Temperature on administering, 102°; in eight hours, 99°, and did not go above this for five days; no redness or tumefaction.

CASE XXVII.—Remittent fever. Four injections, grs. x. each, given at one time; in one hour cinchonized; cinchonism reached its maximum in two hours and a half, began to diminish in four hours; ringing gone in six hours; deafness well marked nine hours after administering; all signs gone at the end of twelve hours; temperature at time of administering, 103½°, reduced nine hours after to 100°. Was treated after this with large doses of quinine internally, temperature never again exceeding 100½°; no redness or tumefaction observed in this case.

CASE XXVIII.—Phthisis. One injection, grs. x.; no redness.

CASE XXIX.—Insolatio comatose. Temperature, 105°; four injections, grs. x. each, immediately; in one hour, temperature, 104°, going down steadily after this; five hours after the injection, temperature 101°; in eighteen hours, normal; patient thoroughly cinchonized and rational three hours after administration; no other treatment adopted, excepting ice-bag to the head; no redness. Discharged cured.

CASE XXX.—Intermittent fever. Seven injections, grs. v. each, at one time; fairly cinchonized in one hour and a half; temperature when administered, 103 ; six hours after, normal; never been above this since; no redness. After treatment, grs. x. quinine internally three times a day.

Case XXXI.—Phthisis. One injection, grs. v.; no redness.

Case XXXII.—Phthisis, subacute pleurisy. One injection, grs. v.; no redness.

Case XXXIII.—Sporadic cholera. One injection, grs. x.; no redness.

Case XXXIV.—Summer diarrhœa. Child ten months old, one injection, gr. j.; no redness.

Case XXXV.—Rheumatism, acute articular. One injection, grs. v.; no redness.

Case XXXVI.—Pernicious anæmia. One injection, grs. v.; no redness.

Case XXXVII.—Carcinoma of uterus. One injection, grs. v.; no redness.

Case XXXVIII.—Intermittent fever. Ten injections, grs. xlv., given at one time; thoroughly cinchonized in one hour, and continued so until eighteen hours after; temperature 102½°; when administered ten hours after, normal; after treatment, grs. xv. quinine internally three times a day.

This salt is a double hydrochlorate (or muriate) of quinia and urea, and is prepared as follows: one equivalent (396.5 parts) of quinia hydrochlorate (muriate) are treated in a porcelain capsule with one equivalent (250 parts) of hydrochloric acid of specific gravity, 1.070, and the solution is filtered. To the filtrate is added one equivalent (60 parts) of pure urea, freed from ammonium sulphate, by recrystallization from *absolute alcohol;* as soon as the urea is dissolved, the liquid is set aside and cooled, so that crystals may form.

After twenty-four hours the latter is transferred to a funnel, drained, washed with very cold distilled water, spread upon plates, and dried at ordinary temperature.

The motherwater is then concentrated and once more allowed to crystallize. The last brown motherwater is allowed to evaporate spontaneously, when all the quinia still present will crystallize out. The final residue is a thick brown syrup, which yields no further crystals, does not freeze even at 18° C., and consists almost entirely of a new chinichine.

Hydrochlorate of quinia and urea crystallizes from hot solutions in hard, white, coalesced, four-sided prisms, without terminal surfaces; on slow evaporation very large crystals are obtained.

At ordinary temperature the salt is soluble in twice its weight of water, forming a dense, straw-yellow solution, unalterable in air. It is neither hygroscopic nor efflorescent; at 70° to 75° C. it melts to a yellowish liquid, hardening on cooling to a yellowish mass; the salt thereby loses ten per cent. of water.

On allowing this to stand exposed to the air, it gradually reabsorbs the lost water, and becomes white again. It is also soluble in alcohol. Ether appears to throw down from this solution a different salt. The salt contains 69 per cent. of pure quinia; the ultimate constitution, however, of the salt has not as yet been determined.

The above investigations consist of one hundred subcutaneous injections of this solution, ranging all the way from two to forty minims each, without a single abscess resulting therefrom, the total number of patients was 38, and total amount of the salt used was 776 grains.

From the above we find that the minimum quantity of the salt necessary to produce cinchonism in an adult malarial case is grs. xxx., grs xl. producing, when given at one time, cinchonism in one hour, the effects lasting about ten hours.

The satisfactory results as shown above make the benefits to be derived from the use of this salt at once apparent, and are: 1st. In the treatment of infantile disorders requiring the use of quinine; 2d. In those cases where cinchonism is desired quickly; 3d. In patients comatose, with a high temperature; 4th. In those cases in which the drug will not be tolerated either by stomach or rectum; 5th. The greater economy, as one-half less is necessary than when given by mouth, and three-quarters less when given by rectum. The solution I use is a transparent liquid of a slightly yellowish hue, of a syrupy consistency, and does not become turbid nor decompose on keeping. It is but slightly acid, and contains the salt in its most soluble form, one minim representing gr. one quinia.

Reports of Hospitals.

COOK COUNTY HOSPITAL, CHICAGO.

Reports of Practice and Peculiarities of Treatment.

Case I.—*Abscess of Liver opening into Pleural Cavity —Death.*

James D. Irish, æt. 50; stone-cutter; admitted to hospital, October 7, 1879; a brother died of phthisis. Was in U. S. regular army for fifteen years, at times being exposed to great hardships and variable temperatures. In 1863 had a very severe attack of inflammatory rheumatism. About the 15th of September last was taken with aching pains through the body and extremities, especially "in the bones," and was forced to take to his bed at once. Had no chill, but an intense fever, an unquenchable thirst, slight cough, burning pain in epigastric region, diarrhœa, the stools were greenish yellow and sometimes nearly black. Previous to patient's admission to hospital these symptoms continued with few remissions.

On admission: temp., 101.8° F.; pulse, 104; resp., 32. Anorexia, nausea, vertigo; skin dry and rough, micturition painful; urine normal color, alkaline, spec. grav. 1020—one hundred and two ounces passed in twenty-four hours.

Left lung, normal; heart normal as to rhythm, but somewhat displaced to left and upward; flatness below a line drawn transversely from right nipple to a point one-half inch below scapula; upper part of right chest slightly dull, with suppressed breathing and moist râles; area of hepatic dulness much increased and extending one inch below umbilicus; pressure over infra-mammary, epigastric and hypochondriac regions, gave rise to acute pain; area of splenic dulness increased. Ordered:

℞.	Quinia sulph................	ʒ ss.
	Acidum mur..................	q. s.
	Tr. ferri chloridi, Tr. nucis vom., ...āā	ʒ ij.
	Syr. ....q. s. ad	℥ ij.

M. S.—ʒ i. three times daily.

October 11, P.M.—Pulse 104; temp. 100° F.; resp. 26. Nausea and vomiting; gurgling in right iliac region.

October 13th.—Friction sound over right infra-axillary region. ℞. Emp. cantharides. Absence of respiratory sound in lower part of right lung; high pitched and suppressed breathing in upper portion, with flatness on percussion at apex.

October 14th.—Tenderness over right hypochondriac region. Over infrascapular region is heard a friction sound with both inspiration and expiration.

℞. Mag. sulph.................. ʒ iij.
Aqua cinnam.................. ℥ ij.
M. S.—ʒ ij. night and morning.

October 17th.—Temp. 99½° F.; coughed most of last night; sputa, white, frothy mucus; hepatic tenderness less; slight friction sound occasionally heard in infrascapular region of right side.

October 21st.—Has been gradually failing; temp. for last four days has not exceeded 100° F.; bordering on collapse; hepatic tenderness increased; area of flatness in right apex of thoracic cavity increased.

October 23d.—Sinking; hepatic tenderness increased and extends to right nipple; dyspnœa.

October 24th, A.M.—Temp., 98.1°; resp., 40; pulse, 120; extremely weak and can only whisper; expired about noon.

Post-mortem, thirty-six hours after death.—Pericardial fluid increased in quantity; heart normal; slight bronchitis in upper lobe of right lung and large bronchi of left lung; right upper lobe somewhat œdematous and compressed; lower lobe carnified and firmly adhered to diaphragm; universal adhesions of right lung to parietes of chest, except small spaces near and along sternum and at apex, which spaces were filled and distended with pus; liver very much enlarged, the right lobe containing an enormous abscess, the upper wall of which was formed by the diaphragm, owing to adhesion of liver and diaphragm. Here was an opening by which the abscess and chest-cavities communicated; one and one-half pints of pus was found in apex of chest-cavity, no pus in abdominal cavity; pus in abscess contained masses of sloughed liver-tissue. In and adherent to abscess walls were numerous blood-vessels, very neatly dissected out. In left lobe of liver were a few small abscesses; cavities contained over one and a half gallons of pus; spleen enlarged, but of normal structure; kidneys normal.

CASE II.—*Abscess of Liver, with Pleuro-pneumonia.—Death.*

J. W., æt. 31; miller; admitted to hospital December 5, 1879. His father died of so-called heart disease; his mother, of a lung disease. He has been, as a rule, healthy. Four days before admission he began to have pain in the right hypochondriac region, which, with intervals of ease, countinued until his admission. He also had headache and vertigo.

Notes on admission: Resp., 28; temp., 98.5° F. Pulse slow and feeble. Skin dry, cold, and rough. Tongue flabby, dry, and coated white. Anorexia, thirst, constipation, sleeplessness, dyspnœa at times, pain in right hypochondriac region. Area of liver much enlarged, the lower line extending down a little below the umbilicus. A distinct murmur was heard with first sound of heart at apex and base. Apex-beat one inch to left of nipple, and sound at base best heard in third intercostal space, two inches to left of sternum. Flatness on percussion over lower part of right lung.

Treatment:

℞. Hydr. chlor. mit........... grs. xij.
Chrt. No. iv. Sig.—One at bedtime.

Also: ℞. Fl. ext. apocynum cannabinum.. ʒ iij.
Syr......................q. s. ad ℥ ij.
Sig.—ʒ i. four times daily.

December 13th.—Area of liver dulness diminished in extent, and lower limit more difficult to outline. General condition improving. Urine normal in amount; spec. grav. 1020; acid reaction yellowish brown color; no albumen, sugar, casts, or sediment.

December 15th.—Area of liver dulness but slightly enlarged. Feet somewhat œdematous.

December 16th.—Temperature, 99° F.; resp., 35; Pulse slow and feeble. Feet very œdematous. Complains of pain in region of heart; find roughening of first sound at apex and base; more marked at former point.

December 17th.—Condition same as yesterday.

℞. Tinc. digitalis.............. ʒ iij.
Tr. ferri chloridi............ ʒ iij.
Syr. ....q. s. ad ℥ ij.
Sig.—ʒ i. four times daily.

December 23d.—Gastric distress on taking food. Feet not less œdematous. Dyspnœa.

December 26th.—Resp., 38; temp., 100° F.; pulse, 84 and weak. To have 5 grs. sulph. cinchonidia four times a day.

December 27th.—General condition not improving. Anorexia, thirst, sleeplessness, constipation, œdema reaching above knees. Dyspnœa.

December 29th.—Same.

January 4th, 1880.—Pulse, 100; temp., 100° F.; resp., 38, and dyspnœa marked; flatulency, especially after eating. Stools daily, but scanty and of whitish color. Appetite somewhat improved; thirst and dyspnœa; orthopnœa. Discontinue all previous treatment, except apocynum cannabinum to promote diuresis. To take four co. cath. pills at bedtime; also pepsin and hydrocyanic acid.

January 8th.—Pulse, 92; temp., 100° F.; resp., 36. Better. Flatulency continues. Stools more copious and darker in color. Thirst; dyspnœa; eyes expressive of fear and distress. Orthopnœa.

January 10th.—Tem., 99; pulse, 84; resp., 40. No change.

January 12th.—Anorexia, sleeplessness, flatulence, thirst, wild look, feeble pulse, orthopnœa.

January 16th—No change.

January 17th.—Weaker.

January 18th.—Sank gradually and died.

Post-mortem, eighteen hours after death.—Emaciation extreme. Abdominal cavity filled with yellowish serous fluid. Liver, especially the right lobe, enormously enlarged, and right lobe contained an immense abscess, filled with bloody pus, mixed with much curdy fibrous substance. In and upon the walls of the abscess lay many of the blood-vessels neatly dissected out. Some pleuritis in right thorax. Base of lung firmly adherent to diaphragm and liver. The diaphragm formed the upper wall of the abscess, which wall was very much attenuated.

Heart, spleen, and kidneys normal. Lower lobe of right lung carnified. Upper lobes œdematous. Left lung somewhat œdematous.

CASE III.—*Stricture of Urethra—Diphtheritic Urethritis and Cystitis—Pyelitis—Suppurative Nephritis—Embolism at Bifurcation of Right Pulmonary Artery—Hemorrhagic Infarction of Lower Lobe of Right Lung.*

James D., colored, laborer, æt. 48, married. Admitted to hospital May 5, 1880. A brother died of phthisis; otherwise, family history good. Has been a beer and spirit drinker for 15 or 20 years, and for past 10 or 12 years has become quite dissipated; was brought from a house of ill-fame to the hospital.

Notes on admission.—Quite weak, pulse 120, temperature, 100° F.; resp., 32. Skin dry, tongue coated white. Dyspnœa; slight cough, expectorations of frothy mucus. Has spit blood in small amount for last three or four days; this came on suddenly. Insomnia; bowels free. Incontinence, with retention of urine. Sibilant and sonorous râles heard over the whole chest.

Heart-impulse increased, and roughened sound at apex with systole.

Treatment.—General and supporting.

May 6th, A.M.—Incontinence, with retention, continued. Subcrepitant râles over lower part of right lung.

P.M.—Pulse, 100; temp., 101° F.; resp., 36.

May 7th, A.M.—Pulse, 120; temp., 101° F.; resp., 40. Patient more stupid.

P.M.—Pulse, 128; temp., 102° F.; resp., 44. Perspires freely and sleeps most of time.

May 8th, 8 A.M.—Pulse, 102; temp., 101° F.; resp., 48. Incontinence of urine. Passes fæces unconsciously.

P.M.—Pulse, 128; temp., 103° F.; resp., 52. Unconscious; breathes stertorously, perspires profusely, and has taken no food for 36 hours.

May 9th, A.M.—Pulse, 120; temp., 102° F.; resp., 46. Same.

P.M.—Temp., 103° F. Died.

Post-mortem, 70 hours after death.—Heart much enlarged by hypertrophy and dilatation (size of ox heart), especially the left ventricle. Serous fluid in pericardium normal. No signs of cardiac inflammation; valves normal. Beneath the endocardium, in both ventricles, were seen numerous small grayish white spots which were marked on the papillary muscles and columnæ carnæ, giving a mottled appearance. Under the microscope the muscular striæ were seen to have disappeared and to be replaced by numerous granules, unequal in size in the muscular fibres. The descending aorta was found much dilated and hypertrophied, its elasticity, transversely, entirely gone. It was of a grayish ash color, and here and there were calcareous plates in its walls throughout its entire length. At the bifurcation of the right pulmonary artery was an embolus, which had closed the lower and nearly closed the upper branch; lower lobe was heavy, full of fluid, which appeared to be mostly venous blood.

The upper lobe and whole of left lung, natural, except for a slight bronchitis. Liver and spleen normal. Stricture at membranous portion of the urethra; also 1½ inches from meatus urinarius. Whole surface of the urethra was in state of diphtheritic inflammation. Bladder much dilated and hypertrophied, its walls being about four times their natural thickness. Bladder contained over a pint of urine, and was in an acute state of cystitis. This inflammation had extended up the ureters, which were dilated and hypertrophied. The kidneys also were involved in the inflammatory process, there being numerous small abscesses in the parenchyma of these organs. The abscesses were from one to three lines in diameter and contained pus. There was also marked pyelitis.

A SOCIETY FOR THE PROMOTION OF CREMATION has been organized in St. Louis, Mo.

Progress of Medical Science.

ESTIMATION OF URIC ACID.—Dr. Pavy, at a late meeting of the Royal Medical and Chirurgical Society, described a method of determining readily and with precision the amount of uric acid voided. It was founded upon the reducing action which uric acid, like sugar, exerted upon the oxide of copper. The ordinary form of copper test was most susceptible of application to the purpose; but the ammoniated cupric liquid which the author had recently introduced for the quantitative determination of sugar was perfectly available. With this test the reduced oxide, instead of falling as a precipitate, was held in solution by ammonia, and a simple decoloration of the liquid occurred as the reduction proceeded. It was stated that the results obtained from observation, conducted with known quantities of pure uric acid, so closely harmonized with the expression, that three atoms of oxide of copper were reduced by one atom of uric acid, as to justify this formula being adopted as the basis of calculation for the process. For the determination of the uric acid in a given specimen of urine, the reducing power was taken before and after treatment with acetate of lead. The first total reducing action was in part due to uric acid, and in part to the small amount of sugar which urine naturally contained. The addition of acetate of lead effected a precipitation of the uric acid; and the reducing power now obtained represented the reducing power of the urine, *minus* that of the uric acid which it contained. By the difference between the two determinations, the amount of uric acid was ascertained. Dr. Pavy also stated, that, according to his observation, the figures hitherto given as representing the amount of uric acid present would have to undergo considerable alteration. Results of analyses were read, showing great variations in the relation between the amount of uric acid deposited and the amount present in the urine, and the acidity of the fluid.—*The Brit. Med. Jour.*, March 27, 1880.

ON THE FORAMINA OF MONRO IN MAN AND THE DOMESTIC CAT.—Dr. Burt G. Wilder, of Ithaca, was to have read a paper on this subject, at the recent meeting of the American Medical Association, but owing to the great pressure of business, the paper was withdrawn. We were, however, enabled to obtain it in abstract form, and the following is a résumé of its most important points: The brain might be described as consisting of a series of cavities, single or paired, surrounded by walls of varying thickness. The ventricular arrangement was least obscured in embryo, and in frogs and salamanders, especially menobranchus, where the walls were thin and the cavities large.

The *ventriculi laterales* were always connected with the *ventriculus tertius* by two orifices usually called the *Foramina* of *Monro*. Although known to Galen, Vesalius, and others of the older anatomists, the existence of these foramina was doubted by Haller and others prior to 1783. *Monro*, secundus, figured and described these orifices in 1783, and they had since then been known by his name.

The description usually given of these openings conveyed the idea that they were notches. The following points were brought out by examinations of the cat's brain: The foramen of Monro in the cat appeared as an elongated oval orifice, 0.5 mm. to 1 mm. wide, and 3 to 4 mm. long. Its long axis lying at an angle of about 45° with the longitudinal axis of the brain. Its cephalic border was the corresponding side of the fornix. Its caudal border was the slightly emarginated cephalic end of the corresponding thalamus. The radial end was the line of union of the fornix and thalamus. Its dorsal end corresponded with the points of attachment of the velum to the cephalic end of the habena, and to the fornix, where it began to curve over the thalamus. Each foramen was an orifice with definite boundaries, capable of resisting the pressure required to force a plaster injection from the infundibulum nearly to the tip of the *cornu temporale.* Such plaster casts were shown us, with the constriction at the foramen clearly apparent. The boundaries of the foramen of Monro in man were essentially the same as in the cat.

The narrow cephalic portion of the ventriculus tertius, into which the foramina open, was entitled to a separate name, and *aula* was proposed as an appropiate designation.

From the middle of the fornix, and at a level with the middle of the length of the foramina in all cats examined by Dr. Wilder, a small oval body was found. This might be called the *tuberculum aulæ.* The writer had also found it in the sheep, and evidences of it in a human brain.

THE TREATMENT OF CONSUMPTION.—In a paper on the treatment of pulmonary consumption, Prof. Péter, of Paris, insists strongly on the value of hydrotherapy. He begins with frictions with dry flannel, then passes to rubbing with cloths dipped in aromatic alcohol, cologne water, or vinegar, followed by dry friction for five or six minutes, and finally advances to the use of the cold sponge. The process is repeated twice daily, immediately after rising and before retiring. He believes sponging to be better than the douche, because it is more easily carried out. The chief points to be observed are, to accustom the patient gradually to the use of cold water, and not to prolong the bath too much at first. Prof. Péter divides the sweats of phthisis into three classes, according to their cause, viz. : ordinary night-sweats, which depend not so much on the pulmonary trouble as on the general condition and the tubercular fever, the sweating which follows high evening exacerbations of the fever, and colliquative sweats. To control the first, he recommends especially sponging with vinegar, combined with the usual internal remedies, such as acetate of lead, tannin, etc. Atropine, he considers unreliable. Quinine is useful for the second form, because it controls the fever. For the colliquative sweats, there is no remedy. For the cough, he gives opium and belladonna in small doses ; he orders pills containing one-sixth of a grain of opium, and one-twelfth of a grain of ext. belladonna, and gives, at first, one at a dose, increasing afterward if necessary. When the cough causes vomiting, he gives one or two drops of tincture of opium before meals, with good effects. When the vomiting seems to be due more to dyspepsia than to the cough, he gives a few drops of hydrochloric acid after the meals. In such cases, alcohol in some form is also useful, but it must be given freely. For the diarrhœa, when it is due to simple intestinal catarrh, as is usually the case at the outset of the disease, he employs subnitrate of bismuth, in connection with a carefully regulated diet. When it is due to the use of cod-liver oil, or to the milk or grape cure, the exciting cause must be discontinued, and the stomach, if overloaded, be emptied by an emetic. When it is due to inflammation of the stomach and intestines, he prescribes opium, nitrate of silver, perchloride of iron, etc., and employs also derivatives to the skin. For colliquative diarrhœa there is no remedy. For controlling the expectoration, he has found the balsams, glycerine, and kermes, to be the best remedies. For hæmoptysis, he recommends in the first place, the use of emetics, and explains their action on the theory that they excite a reflex action through the sympathetic, which causes anæmia of the lungs, and controls the hemorrhage. When patients have been greatly reduced by the hæmoptysis, he has found quinine and ergotine useful.—*Allg. med. Cent. Zeit.*, February 25, 1880.

ON THE STRUCTURE AND DEVELOPMENT OF TUBERCLE.—In a paper presented to the *Académie des Sciences*, of Paris, MM. Kiener and Poulet stated as follows the results of their investigations on the structure and development of tubercle in men and animals :

A. *Structure of tubercle in the connective-tissue substances* (serous membranes, pleural and peritoneal new membranes, pia mater, articular, synovial membranes, periosteum, bony marrow, lymphatic glands).

In these tissues tubercle may be simple, conglomerated, or infiltrated. In structure, it presents two types : the cellular and the fibrous.

I. *Cellular tubercle.* 1. *Simple form.*—In its simplest form the tubercle is almost or entirely invisible to the naked eye, and is formed by a sphericle or fusiform enlargement of a blood-vessel, or more rarely of a lymphatic vessel, and by an agglomeration of a number of cells around the enlargement. When the vessel is a capillary with a single coat, the vascular enlargement is formed by hypertrophy and hyperplasia of the endothelial cells of a limited portion of the vessel. These cells undergo a vitreous degeneration and become fused together into a solid cylinder, a transverse section of which presents the appearance of a giant cell, with a border of nuclei (vitreous capillary). Around the swelling a certain number of migratory cells are grouped, along with some fixed connective-tissue cells in a state of hyperplasia ; these latter elements sometimes form around the vessel a complete perithelium, constituted by distinct elements. When the capillary has two or three coats, the enlargement is produced : first by an active proliferation of the endothelial cells, which assume the arrangement of a stratified epithelium, and the most internal of which become fused together into a vitreous mass of a very irregular form, that must also be regarded as a variety of giant cell ; secondly, by the formation of an embryonic connective tissue at the expense of the external tunic. The vessel is thus transformed into a solid cord, a transverse section of which gives the appearance known by the name of *tubercular follicle.*

2. *Conglomerate form.*—The conglomerate tubercle may be larger than a millet-seed, and is formed by an interlacement of capillary vessels that have undergone the changes just described. When such a nodule is separated into its elements, these are found to consist of more or less brittle, nodular, ramified strands, consisting of a fibrous tunic, with opaque and yellowish contents. A section of the nodule reveals an agglomeration of rounded or elongated follicles with epithelioid contents, united together by a fibrillated connective tissue, in which vitreous capillaries are disseminated.

3. *Infiltrated form.*—The infiltrated tubercle is

formed by a granulation tissue provided with a rich network of capillary blood-vessels, most of which contain multiple layers of endothelium, while some are transformed into vitreous cylinders, or into follicular cords.

II. *Fibrous tubercle.*—A series of intermediate forms establish the transition from the cellular to the fibrous tubercle, and show that these different products are due to the same process, which may give rise to different types of alteration of the blood-vessels. According as the progress of the tubercle becomes more chronic, a fibrous neoplasm is substituted for the embryonic neoplasm, the tendency to the development of giant cells becomes less pronounced, the periarteritis predominates over the endarteritis, and even the obstruction of the lumen of the vessel is due more to a fibrous thickening of the internal tunic than to proliferation of the endothelium.

B. *Structure of tubercle in the glandular organs.*—In the glands the interstitial tissue may alone be involved, and the resulting tubercles will then be analogous in structure to those of the connective tissues. Sometimes, however, the glandular element also takes part in the development of the tubercle. Thus, for instance, the seminiferous tubule in the testicle, or the bronchiole in the lung, filled and distended with the products of epithelial proliferation, or with pus, forms a sort of nucleus, around which the interstitial tissue, transformed into an embryonic tissue, presents the characteristic appearances of vascular alteration—vitreous capillaries and follicles.

C. *Development and course of tubercle.*—In the course of development the tubercular neoplasm passes through two phases:

1. *Nodular formation.*—The nodules are developed most frequently in the course of tubular conduits—blood-vessels and lymphatics, glandular tubules and excretory ducts—and are formed partly by proliferation of the endothelial or epithelial cells, and partly by a new formation of embryonic or fibrous connective tissue, at the expense of the external tissue of the conduit.

2 *Hypertrophic and degenerative phase.*—The various anatomical elements of the newly formed embryonic tissue, and the pre-existing elements of the normal tissues, manifest a tendency to undergo hypertrophy, to fuse together to form giant cells. This hypertrophic tendency is manifested by preference, and first shows itself in the epithelial elements of the glands, and the endothelial elements of the vessels. It terminates, finally, in a special vitreous degeneration of these anatomical elements and obliteration of the vessel. This, in its turn, entails fatty degeneration, and irremediable destruction of the tissues.—*Gazette médicale de Paris*, Feb. 28, 1880.

Hyaline Degeneration of the Lymph Glands.—Under Von Recklinghausen's direction, Dr. Wieger, of Strasburg, examined the lymph glands in a large number of cadavers, and found, in thirteen cases, a peculiar alteration of the smallest blood-vessels of the glands. The affected vessels were changed into hyaline tubes, the walls being greatly thickened and the lumen narrowed. In the more advanced cases, spots of calcification were found in the hyaline tissue. The hyaline material was regarded as colloid in nature, and was thought to arise from a cellular infiltration of the vascular walls. The etiological influence at work had been probably circulatory disturbances of dyscrasic or senile origin. In two of the cases there was a diffuse hyaline transformation of the gland substance proper. In both of these cases, multiple nodules were found in different organs, which clinically and anatomically resembled acute tuberculosis very closely. Histological examination, however, showed that these nodules were only small inflammatory foci, which were likewise partly transformed into a homogeneous, hyaline material. The hyaline change in the lymph glands was regarded as the primary lesion in these cases, on account of the large size of the glands and the presumptive age of the affection. The multiple, tubercle-like nodules were thought to be due to metastases.—*Centralblatt für Chirurgie*, March 6, 1880.

◆

Dr. Tanner's Fast.—Dr. Tanner was in poor condition on August 4th, at date of this writing, and there seemed to be some prospect of his not lasting through the forty days, which end at noon, August 7th. Since a week ago he has failed in strength very noticeably. He has not walked much, but has kept up daily rides. He lies most of the time on his cot, where he curls himself up, and covers himself with blankets. He seems to suffer, at times, from the cold. His face wears an anxious, suffering look; his complexion is dusky and sallow. His eyes are bright, however, and all his senses are acute. His hands do not show much emaciation, but his coat and trousers hang about his frame very loosely. His skin has generally been dry, and he took a vapor bath July 29th, to start its action, but with not much success. Auscultation, on August 1st, showed that his lungs were normal. His pulse, respiration, and temperature have also been normal. The dynamometer has steadily registered about eighty kilogrammes. During the past week, his stomach has given him much trouble. There has been a regurgitation of bile, with frequent attacks of nausea; these sometimes ended in retching and vomiting. The vomited matter consisted of biliary matter, mucus, epithelium, and a few blood-corpuscles. In order to relieve the gastric distress, he has taken warm water, iced carbonic acid water, and mineral waters, but they did little good. Another difficulty that has increased in the last week, is tympanitis. His abdomen has become distended with gas, and he frequently belches wind or passes it per anum. Dr. Tanner's mind has been somewhat more irritable, but he has had nothing like delirium, or wandering. He had slept pretty well, though his periods of rest were short. The interest in his condition increases toward the last, as shown by the number of visitors. A changing stream of twenty or thirty are in the hall all the time. On August 2d, a telegram of encouragement was sent from Paris by some one. Daily bulletins of his condition were sent to London and Paris, and column notices have appeared in the daily press. Dr. Tanner weighed, on August 2d, 125½ pounds, a loss of 4½ pounds since July 26th. He has taken from sixteen to twenty ounces of water, and voided from ten to fifteen ounces of urine every day. Dr. Tanner's greatly enfeebled condition toward the last throws some doubts over the prospect of his holding out. It adds to the confidence of those who believe in his honesty.

The Canadian Medical Association.—The thirteenth annual meeting of this association will be held in Ottawa on the first Wednesday of September, 1880, under the presidency of Dr. P. Howard, of Montreal. It is expected that the meeting will have more than usual interest.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, August 7, 1880.

PHARMACIST AND PHYSICIAN.

In discussing, in a previous number, the relations which should exist between physician and druggist, we alluded to some of the charges of unfair dealing which were referable to the latter. Pursuing the consideration of the subject we take up the other side of the question and examine the difficulties with which the pharmacist has to contend in his attempts to reconcile the differences between himself and the physician.

First of all, he claims that he must make a living. He naturally looks to the physician to help him do this. But he maintains that the profit from prescriptions, large as it is, is not enough to enable him to carry on his business with a decent margin. That physicians are as much in the habit of interfering with the business of the pharmacist as is the latter with that of the physician. For instance, the latter will frequently be asked the probable price of the prescription, and will be coaxed into the expression of opinion as to the extravagant charges of compounders of drugs; while others will purposely narrow the profits on prescriptions to the smallest limits, on the plea of saving money for their patients. They also claim that skill in compounding, and care in the selection of pure articles, should be duly appreciated and paid for accordingly, in fact that the true interests of the patient and the physician centre in the encouragement of pure and legitimate pharmacy.

Great, however, as these evils appear, they are small in comparison with the supplying of their own medicines by the physicians. This is virtually taking all the legitimate business from the hands of the pharmacists and reducing them to the level of mere venders of fancy articles and patent medicines. Again, it is claimed that the compounding of prescriptions is also directly interfered with by the wholesale manufacture of all sorts of pharmaceutical preparations, and which are not unfrequently advertised in the daily newspapers the same as other proprietary medicines. These are made in large variety, and each physician having his favorite manufacturer, insists that the latter's preparation be used in the prescription. This not only necessitates the breaking of a package for a small quantity, with the risk of spoiling the remainder of the preparation before a similar prescription is called for, but requires that a large number of such medicines be kept in stock. The margin of profit on these articles is generally so small, that in case there was a chance of selling out the entire lots while fresh, the business venture would be a very ordinary one. The manufacture of many of the most important preparations is more or less in the hands of wholesale men, who apparently leave the retailer with nothing better to do than to handle the goods in smaller lots for an inconsiderable margin of profit.

In looking at both sides of the question, and in attempting to reconcile the interests of the druggists and physicians, we come upon a very difficult problem. There is so much interdependency that it seems difficult to attack one point without disturbing the entire line. The physician is bent on preventing interference with his legitimate functions, looks upon counter or other prescribing as an outrage, while the apothecary is interested in checkmating the physicians who insist upon prescribing their own remedies, and who do other things which tend to interfere with the legitimate practice of higher pharmacy. As soon as the pharmacist is as competent to prescribe as is the well-educated physician, and as soon as the latter is as capable a compounder as is the skilled pharmacist, then the conditions of each will be interchangeable. As it is, this is impossible. And both professions are indispensable to each other. The physician cannot afford to be his own dispenser. As stated by a correspondent in a previous issue, this would be a long step backward in the progress of medicine and in therapeutics. The physician who by such means would narrow himself to the use of a few convenient preparations would become the merest machine prescriber, and his therapeutical aspirations would be narrowed to a rigid procrustean rule. In many cases he would be prescribing remedies of the character of which he knew nothing and of the purity of which he knew less. The physician owes to pharmacy the most cordial aid, for to it he must look for the solution of many problems of chemical composition, for the guarantee of accurate measurements of quantity, for absolute purity of material, and for strict compliance with the directions of the prescriber. These conditions are always fulfilled by the conscientious pharmacist, and such should always be sought out by the physician. The mere counter-prescribers, patent medicine jobbers, should be left to themselves, and pains should be taken to prevent our patients from going to such establishments. As has been previously suggested in these columns, the physician has as much right to prescribe the man who shall put up the medicines as the medicines themselves. When once a druggist is caught at counter-prescribing, the physicians of the neighborhood should take pains to give him as little opportunity as possible for exercising the questionable calling.

The suggestion that co-operative pharmacies be established in different neighborhoods, each establishment being supported by a corps of prescribers, is a good one, but in view of the excellent pharmacists scattered all over the city, men who are competent, upright, and who would do everything to help the physician, it is hardly necessary.

There is perhaps a better understanding necessary as to the price to be charged for prescriptions. While it is necessary that skilled labor should be recompensed, it is also important that some of the patient's money be left for the physician. If no more than a reasonable profit be demanded by the pharmacist, much cause for the dissatisfaction on the part of physician and patient would be removed. It is well known that some preparations are very expensive. In such cases every encouragement should be given to the pharmacists to use the right drug regardless of the price asked, and the physician should be ready to explain the reasons for such charges to his patients. Such a course could not fail to be satisfactory to all concerned, and specially so to the patient, who above all is interested in obtaining the pure article.

If such a general course is pursued, there will eventually be two classes of drug stores, one devoted principally to the higher branches of pharmacy, the other to the sale of patent medicines, hair-dye, and bug powder.

TANNER'S FAST.

The exhibition at Clarendon Hall will come to a close to-day, if it has not done so sooner, and the attenuated experimenter, doubtless with much satisfaction to himself, returns to his normal diet. The principal items regarding his performance, that possess any scientific interest, have been published in The Record, and do not need repeating here. There has been, however, so much public comment from all sources upon the matter, that we are excusable in discussing the subject briefly now.

It is undoubtedly the popular opinion that Dr. Tanner is honest, and that he eat nothing during the time of his fast. We are not disposed to deny the justice of this judgment. There is nothing in the character of the faster which would lay him under any particular suspicion. His past history has been that of a man of respectable character and of strong self-will, who has endeavored to lift himself out of an unsuccessful medical career by fanatically advocating various theories on the subject of electricity and fasting. In his present experiment he has been watched quite constantly by three sets of men, whose honesty or intelligence it is not fair to impugn. We do not think it strange, therefore, that he is generally believed to have kept the fast as he claims to have done.

The are, however, certain other elements in the matter which rob his experiment, whether genuine or not, of nearly all its value. In the first place, it cannot be positively denied that he did not take any food. One set of his watchers was confessedly in sympathy with him, and wished strongly for his success. The regular physicians were not continuous in their attendance at first, and he was not always under their eye. Dr. Tanner was taken out to drive, went to the photographer's and the barber's, and took occasional strolls about the neighboring square. Finally, his physical condition was considerably different from that which all past experience has shown to follow abstinence from food. His surprising vigor, his occasional gain in weight, his comparative freedom from suffering of any kind, are phenomena which are not easily explained under accepted physiological laws. If to this is added the manner in which the experiment was conducted—a manner which had the mixed character of a variety show and a patent-hammock advertisement—we feel sure that the profession will agree that little practical or scientific value can be given to the alleged fast.

Apart from this view of the matter, there were several unpleasant features connected with the exhibition. There was, for instance, an attempt all along to create the impression that the regular physicians were inimical to Dr. Tanner; that they believed the feat of fasting forty days a physical impossibility, and that his success in performing such a feat would be a blow to scientific medicine. This absurdity was fostered by a few indiscreet individuals who felt it their duty to appear in the daily newspapers. There has been, however, no physician, so far as we know, who has denied the possibility of accomplishing the fast. All that has been desired was that the experiment should be carefully conducted, so that some benefit might accrue to science in its performance.

In denying any practical value to Dr. Tanner's performance, we might make one slight exception. The widely advertised announcement of the fact that a person had comfortably passed many days without food will lead many other persons to try the same thing, to a greater or less extent. If this is done under the guidance of good physicians, it may secure some definite knowledge of the therapeutic effect of fasting. There is no reason why it should not be of occasional value in cases of digestive trouble, obesity, etc. With the comfort of having given an impulse to this somewhat doubtful branch of therapeutics, and of having gained the ephemeral notoriety which he craved, we recommend Dr. Tanner to return to the simpler joys of his electrical baths and a normal diet.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 17, 1880.

VICE-PRESIDENT, FRANK H. HAMILTON, M.D., LL.D., IN THE CHAIR.

THE paper of the evening was by DR. AMBROSE L. RANNEY. Subject:

ARE THE BENEFITS TO BE DERIVED FROM INTERNAL URETHROTOMY, AS NOW ADVOCATED FOR THE CURE OF STRICTURE, COMMENSURATE WITH ITS DANGERS?

Dr. Ranney divided the modes of performing internal urethrotomy into two kinds: the one which divides the stricture slightly, and the other, which cuts it deeply.

A large number of authorities were quoted, showing that cutting operations did not furnish, except in a few cases, the safest or best method of treating the strictures. Dr. Ranney could positively state that internal urethrotomy did not always give satisfactory results as regards cure. A list of the possible sequences of the operation was given: hemorrhage, fever, curvature of the penis, etc. The view that the operation is not often necessary, and is now performed much too frequently, was taken, and supported by quotations from a large number of authorities.

The operation was then discussed: 1st, as regards its elements of popularity, Dr. R. referred to the great increase in the cutting operation, which had occurred in the last few years. He took issue against the views of the new school of urethral pathologists, who cut every urethra which is not large enough to admit a sound of a certain arbitrary size. The arguments of this school regarding the value of the dilating urethrotome were stated. Dr. R. said that at present their doctrines seemed to be eagerly embraced by many young men; that instrument-makers were selling large numbers of urethrotomes to medical graduates. He deplored this fact as one likely to bring danger to patients and reproach to surgery.

The elements of danger in the operation were then given.

Different sets of cases, reported by Dr. F. N. Otis, were analyzed with reference to accidents or sequelæ. In one set of cases there were: hemorrhages, 4; rigors, 6; prostatic abscess, 3; diphtheritic exudation, 3; perineal section necessary, 1; gonorrhœal rheumatism, 1.

The cases of Dr. Pease, of Syracuse, were analyzed and the per cent. of complications given.

Dr. Ranney said that in the cases reported by Dr. Otis and some of his followers there was a better showing as regards hemorrhage than the facts really warranted. This he inferred from a statement of Dr. Otis's, that hemorrhage was not put down, unless it reached a certain advanced measure of severity. Furthermore, Dr. Otis had not reported cases in which he had operated for other surgeons. This was to be regretted, for Dr. R. had heard of a number of bad results in such operations.

Dr. Ranney asserted that, as yet, there were not enough full statistics regarding the accidents that follow internal urethrotomy to give a correct idea of the dangers of the operation. Dr. Sands's statement that three deaths had occurred in New York City hospitals from the operation was quoted; unfavorable statistics from Mr. Berkley Hill were also given. Dr. Ranney related a case that he had seen in 1871, and another in which he had himself operated; both of them died. Another case, in which atrophy of the penis followed the operation, was quoted. Cases lost by Drs. Peters and Post and Otis were mentioned. The many fatal cases in the hands of French surgeons were enumerated. Sixty-six fatal cases in all have been verified. Reviewing the whole, the point was made that the bad accidents formed a larger percentage than is generally supposed.

The benefits claimed by the operation were enumerated:

1st. That gleet is the signal which nature hangs out to indicate a urethral stricture. That a removal of the cause furnishes the only means of cure for such gleet.

2d. That certain obscure symptoms, such as neuralgic pains, pains in the back and limbs, etc., are dependent on stricture, and demand an operation.

3d. That all methods of treatment, except by urethrotomy, will generally be found useless.

4th. That the dilating urethrotome effects a radical cure.

5th. That the operation is free from danger, and that the benefits derived from its use recommend it to the profession to the exclusion of other methods of treatment.

6th. That the records of the cases so far announced support all of the above points.

Dr. Ranney then discussed the foregoing points in detail. In regard to (1), it involved the question of, what is a stricture? The definition given by the new urethral pathologists is, that there is a stricture whenever the urethra will not admit a sound of a certain arbitrary size. Much that has been said on this point is dogmatic and cannot be fairly substantiated. Authorities were quoted showing different views on the subject of what is a stricture and its relation to gleet.

(2.) The question of how many symptoms that are asserted to be reflex really are so, is a very wide one. But it may be said that when a urethra which admits a tolerably large sound, or in which there is gleet, is cut because a man has pain in the back or in the foot, it is doing a dangerous operation on the basis of an unproved theory. More conservatism is needed.

(3.) Regarding this point, Dr. Ranney thought that the alleged absence of tendency to a return of stricture after cutting, was exaggerated. He was certain, on the other hand, that some strictures had been cured by dilatation. The annoyance of using occasional sounds is slight, and he believed it should be advised rather than subject the patient to a hazardous operation.

(4.) This point was accepted, except in a certain proportion of cases. He did not think that internal urethrotomy should ever be employed when the stricture is more than four inches from the meatus.

(5.) Regarding the alleged freedom from danger, statistics were given at great length. In the 915 cases collected by Dr. Gregory, there had been 46 deaths, or 5 per cent., a fatality which almost equals that for perineal section. Other accidents, especially that of hemorrhage, were very alarming, and the facts led Dr. Gregory to ask, in making his conclusions, whether internal urethrotomy ought ever to be performed. Dr. Ranney then gave an analysis of 240 cases. In these, hemorrhage occurred in 5½ per cent.; rigors, 7 per cent.; deformity of the penis, 4 per cent.; death, in about 2 per cent. In 43 reported cases at the Hospital of St. André, there was hemorrhage in 36 per cent.; urethral fever, 59 per cent.; rigors, 36 per cent.; abscess, 9½ per cent.; death, 20 per cent. In 68 cases at the University College there was hemorrhage in 7 per cent.; urethral fever and rigors, 20 per cent.; abscess of perineum, 11 per cent.; curvation of penis, 4 per cent.; orchitis, 4 per cent.; pyelitis, 3 per cent.; death, 5¾ per cent.

Statistics of 16 cases gathered from other sources show a mortality of 5 per cent.

Statistics show a rapid increase in the percentage of deaths when the operation is below three inches from the meatus. Urethral fever seems to occur oftener in Europe than in this country, though rigors are just as frequent here.

The results of a study of 200 cases from private case-books of surgeons of this city, showed many unfavorable accidents and complications. Dr. Ranney had heard strongly unfavorable opinions as to internal urethrotomy from a number of prominent surgeons of the city.

In conclusion, the following rules regarding the operation were laid down:

1st. Seldom resort to it; never, except the stricture be of traumatic origin, resilient, or at the meatus.

2d. Never perform internal urethrotomy if the stricture is more than four inches from the meatus—three inches is perhaps better.

3d. In strictures of the deep urethra, where ordinary methods of dilatation fail, external urethrotomy is the best operation to adopt.

4th. Dilatation of strictures will be found practicable in the majority of cases, and in many cases will entirely relieve all the symptoms.

5th. Internal urethrotomy should only be performed when the stricture has been treated by other means without avail.

The paper being open for discussion,

Dr. Dowell, of Texas, said that he had had one death from internal urethrotomy in over one hundred cases. He had been in the habit of using an ovoid metallic retention catheter with very satisfactory results. He learned that Dr. Otis was opposed to the use of the catheter; but he did not agree with him. In Dr. Dowell's experience it had acted well.

Dr. A. S. Hunter said that he used a dilating urethrotome, though he laid it aside when he reached the bulb. He had not been so much afraid of hemorrhage since he had used hot water. Just before operating, he suspended the penis in hot water; he did the same with the instruments. He also left the instrument in for five minutes. The deeper strictures he dilated either with the ordinary sound or, better, with a dilator which resembled the Otis dilator except that it was curved. Dr. Hunter then showed his dilator, by which more expansion could be given at the point than at the heel, even on the curve. He also described an instrument for arresting urethral hemorrhage. Since he had used hot water, he had had no occasion for it, however.

Dr. T. H. Burchard said that he had performed internal urethrotomy fifty nine times up to 1876. Since then he had performed the operation very rarely, and expected to perform it still less. The statistics of eighty-three internal urethrotomies were given. In these there were total suppression of urine in two, and extensive hemorrhage in three. Dr. Burchard considered internal urethrotomy unjustifiable except when there is great resiliency, or where the stricture is very gristly and cartilaginous, the result of traumatism or long-continued inflammation. The vast majority of cases could be treated much more scientifically and safely by dilatation.

A case of hypospadias, and another of double curvature, due to internal urethrotomy, were related.

Dr. White said that his experience had been very different from that of Dr. Burchard. He had met with few accidents, and the results had been satisfactory.

Dr. F. H. Hamilton spoke of the deep importance of the subject under discussion. He referred to his early teaching regarding it. He was first taught that traumatic strictures were incurable, and that any cutting operation made strictures traumatic. He was then taught that divulsion was the best method. His faith in this was soon lost. He then became acquainted with Dr. Dudley's method, in which there were no instruments used whatever, but simply antiphlogistic measures, with rest in bed. Taking the hint from this, he had always since then employed only rest in bed, with diet and gradual dilatation. He never used any cutting instrument whatever. He believed that the internal urethrotomy of early life meant stricture in old age. Dr. Hamilton had never in his whole life had a fatal case in his treatment of strictures, and all of them had been overcome by gradual dilatation.

Dr. A. C. Post spoke of the fatal case of internal urethrotomy referred to by Dr. Ranney. He had used a Maisonneuve's instrument at that time. He should not use one again. He believed that internal urethrotomy should be performed in obstinate strictures in the antescrotal portion of the canal. Dr. Post had not seen any bad cases of hemorrhage. With regard to wearing a catheter after urethrotomy, he said that he thought the practice a bad one; though if a choice is to be made, the solid silver catheter is the best.

Dr. S. Caro quoted, with approval, the teaching of a celebrated Italian professor, never to use any instrument for stricture. He, himself, used bougies made of guitar strings. A small one can be introduced. It swells up, and when it is withdrawn, a larger one can be put in. Dr. C. related two cases now under his care, which had been operated on two and three years ago by celebrated specialists. The strictures had now returned.

Dr. Ranney, in closing the discussion, said he did not wish it understood that he totally condemned internal urethrotomy. But he did condemn, absolutely, internal urethrotomy below four inches from the meatus. He regretted that a number of New York surgeons, who had told him that they agreed with his views, were not present to confirm the statements he had been making as to a growing distrust among many that internal urethrotomy is an operation attended with much more danger and less advantages than is generally supposed.

The Society then adjourned to the third Thursday in September.

The Discovery of Spontaneous Horse-pox in a Parisian stable, is an event of considerable importance, as the disease is quite a rare one. Since horse-pox is supposed by many to be identical with cow-pox, its discovery furnishes an opportunity to get fresh vaccine lymph. In the present case, the disease has been inoculated into some heifers, the eruption carefully watched, and other vaccinations and revaccinations made from it.

THE NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 27, 1880.

Dr. H. B. Sands, President, in the Chair.

Dr. Erskine Mason reported a case of

FISTULA OF STENO'S DUCT

following gunshot wound, successfully treated by dissecting up the fistulous extremity of the duct and conducting it into the mouth, after the method of Langenbeck, with some remarks upon the treatment of salivary fistulæ.

In September, 1870, he was called to see a boy, æt. fifteen, who had been wounded by the accidental discharge of his gun, which was loaded with buckshot. A large, lacerated wound of the right cheek had been made, which freely communicated with the mouth and extended from the zygoma to the symphysis of the jaw. The lower jaw was fractured transversely just below its neck, and the ramus considerably comminuted as far as its angle. Several of the teeth had been removed, while the tongue was but slightly wounded. The inferior dental nerve was exposed for an inch or more in its course, and presented a ragged appearance. Hemorrhage had been quite profuse, but was arrested by Dr. Jay, who was in the vicinity at the time of the occurrence of the accident. The wound was dressed, and on the 11th of October it was all closed, save a small opening which communicated with the mouth and readily allowed the passage of a probe, and through which some saliva was flowing.

Oct. 21st.—The patient complained considerably of saliva escaping from the wound on the cheek while eating. Application of nitrate of silver was made to the fistula at that time.

Nov. 29th.—Nitrate of silver was again applied to the fistula, which, however, gave but slight annoyance. The flow of saliva, however, finally increased and become a source of great trouble, and in September, 1871, there were two openings from which saliva trickled and produced some excoriation of the face. These openings were but a few lines apart, and seemed to be a little below the site of Steno's duct, though the location was close to the spot where the duct enters the mouth, as was readily determined by a very fine probe which could be made to enter the canal from within the mouth. The probe could be passed only just within the orifice when it met with an obstruction. These fistulæ were situated in a track of cicatricial tissue. In operating Dr. Mason preferred the method which Dr. James R. Wood had employed in two cases, namely, cutting down upon the duct at the site of the fistula and turning it into the mouth. The operation was performed Feb. 24, 1871, assisted by Dr. Jay. The duct was found by laying open the fistulous tracks, and with a fine probe as a guide, dissecting out the cicatricial tissue around the fistula, freeing the extremity of the duct, and turning it in through the opening into the mouth. The external wound was then closed with wire sutures. The upper portion of the wound healed at once very kindly, though at the lower portion there was some suppuration, but it soon ceased and the wound healed, leaving the patient free from salivary fistula. At the time of the operation he did not know that he was operating according to a plan suggested and adopted by Langenbeck in the treatment of these fistulæ. When the operation was feasible he commended it to the attention of the surgeon, though in many cases, no doubt, a more simple procedure may effect a cure.

Dr. Mason then referred to cases of spontaneous closure of salivary fistulæ. Reference was then made to some of the earlier methods adopted for the cure of these fistulæ. Perhaps of all operations thus far resorted to, the one which would seem applicable to many cases, which was simple in its procedure, and devoid of the unpleasantness necessarily attached to the seton, was the one devised by the late Dr. Homer. The operation had been described by Dr. H. H. Smith in his work on Operative Surgery, as follows: "The patient being seated with the head well supported by an assistant, a strong wooden spatula is introduced within the cheek of the affected side; this is held firmly by an assistant. The wound being then slightly elongated by incising its sides in the line of the zygomaticus major muscle, a round punch, like that used by saddlers, should be placed over the fistulous orifice, care being taken to avoid the anterior of the masseter. Then on pressing the punch firmly against the spatula within the mouth, a piece of nearly the entire thickness of the cheek will be removed, and a fresh opening made directly into the mouth. The external wound being closed accurately with sutures and adhesive strips, will usually heal kindly, and the internal opening be found to give free vent to the saliva.

Dr. T. M. Markoe referred to Dr. Van Buren's case, on the person of an officer of the army upon whom several operations had been performed, but that which finally proved successful was one in which the integument surrounding the external fistula, was, by a circular incision, dissected up in such a manner as to leave the fistula terminating in the raised portion. That raised portion was turned into the mouth through an opening, and the wound behind it closed with sutures. It seemed to Dr. Markoe that that operation was almost the only one suitable to the class of cases which was the most difficult to manage. As was well known, there were two classes of cases: one in which the ducts were opened upon their sides, the wound allowing the saliva to dribble outside while the opening of the duct into the mouth remained patent, and the other when the duct was destroyed entirely (no hope being entertained of utilizing its distal portion), and when the proximal portion of the duct terminated upon the external surface of the cheek. To the latter class of cases he thought the operation of turning the integument, containing the external fistula, into the mouth, was well applied; and that it was a beautiful and scientific procedure.

The President referred to a case in which he established a fistula in the mouth of a patient sent to him several years ago by Dr. Rider, of Rochester. From some unknown cause she had obliteration of Steno's duct near its orifice, and, as a result, there was a very considerable dilatation of the duct itself, causing a prominent and disfiguring elevation on the cheek. In that case he ran a platinum wire through a corresponding projection in the mouth, connected it to a battery, and divided the intervening tissues. The result was an immediate subsidence of the external swelling, and at the end of two months the deformity had not reappeared; but what the ultimate result was he did not know.

VESICAL CALCULUS—BILATERAL LITHOTOMY.

Dr. A. C. Post presented a flattened oval calculus, with rough surface, which measured a little more than an inch in its longest diameter, and weighed

149 grains. It was removed from a boy 16 years old, whose genitals were those of a boy of twelve rather than sixteen. The bilateral operation was performed after making the incision into the neck of the bladder, the screw dilator was introduced, the opening enlarged, and the stone readily extracted. An interesting feature of the case was that there had been no dribbling of urine whatever. During the the first twenty-four hours after the operation the urine passed through the wound, and then it began to pass in part through the penis. There had been no elevation of temperature.

CANCER OF THE RECTUM—PROCTECTOMY.

Dr. Post also presented a portion of the rectum removed from a man fifty-three years of age, who looked like a man seventy years old, and who had been conscious of irritation of the rectum only about three months. On examination a tumor was found occupying the rectum on the left side, toward the posterior part, about two or three inches in diameter, and involving not more than two-fifths of the circumference of the bowel. Regarding the case as a favorable one for proctectomy, he made an incision upon each side of the sphincter, divided the levator ani muscle, drew the anus down, and then removed the diseased portion, including about three-fifths of the circumference of the rectum. The remaining portion he attached to the integument. It was fifteen days since the operation was done, and the pulse at no time had reached 100, nor had the temperature reached 101° F. The patient was troubled with slight looseness of the bowels, but otherwise the case was progressing favorably. The elevated portion of the intestine had already descended almost to the level of the skin. The evacuation from the bowels took place without distress.

Dr. Post also exhibited a drawing of a very marked deformity, occasioned by an application made by a cancer-doctress for what was supposed to be cancer of the upper lip. The paste had destroyed the upper lip almost entirely, and he proposed to perform a plastic operation to correct the deformity.

GUNSHOT WOUND OF THE HEAD—NO SYMPTOMS—SUBSEQUENT DEATH FROM MENINGITIS.

Dr. T. M. Markoe presented specimens which were especially interesting in connection with one presented by Dr. Geo. A. Peters, at a previous meeting. (See minutes of stated meeting for March 23, 1880.) The specimens consisted of a portion of the skull and the dura mater removed from the body of a soldier who, a little more than two months ago, in a fit of melancholia discharged a pistol against his right temple. The ball which it carried was, probably, of some size above 22, the calibre commonly employed. Not being satisfied with the effect produced by the shot, he proceeded to cut his throat, which effort was as ineffectual as his first. The throat wound was not serious, and the head wound was not accompanied by any symptoms. The external wound of the head was exceedingly small. He recovered from the wound in the throat, and, in the meantime, the wound in the head was regarded as trifling. The bullet was not found. The wound on the head had entirely healed. At the end of five weeks he began to complain of pain in the back part of the head; especially was the pain extremely severe in the muscles of the nuchæ, and during the last three or four weeks of his life his suffering was intense. His temperature did not rise much above the normal, and it was difficult to appreciate the exact nature of the case. The symptoms increased in severity, coma appeared, and shortly afterward there were symptoms of compression, as if from the exudation of morbid products within the skull, and the patient died.

The portion of skull removed showed the point at which the wound took place, and the internal border of the opening was somewhat blackened by the lead. The ball was found, somewhat disfigured, lying upon the dura at a point opposite to that at which it passed through the bone, and in a rounded depression about half the size of a large pea, which had caused a corresponding depression in the brain-substance. On the inner surface of the dura mater was a corresponding elevation, made partly by the ball and partly by the piece of the internal table which had been carried before it. The process of normal repair had been going on about the depressed portion of the dura and about the bullet, and the membranes surrounding the wounded part were perfectly normal. In the posterior part, along the dura mater which covered the pons, and backward between the lobes of the cerebellum, there was a considerable quantity of purulent and fibrinous exudation—distinct evidences of inflammation. Careful search was made to see whether there was anything like a continuity between the two conditions found, but it did not appear. It was a case which illustrated how apt nature was in adapting herself to very serious lesions. The bullet did not apparently perforate the dura mater; if it did, the perforation had been sealed by the process of repair. It was nearly nine weeks since the wound was received.

Dr. Weir referred to a case seen by him during the war, and which is recorded in the Surgical Reports issued from the Surgeon-General's office, of a private soldier who was wounded by the entrance of a Minié bullet through the left temporal bone into the brain. No cerebral symptoms followed, except some facial paralysis. What was supposed to be the entire bullet was extracted the next day from the brain, one and one-half inches from the surface. The patient was discharged from the hospital in good condition and with wounds healed. Two months afterward he got drunk, and a day or two following had convulsions and other cerebral symptoms, and died. The autopsy showed two-thirds of a musket-ball resting on the sella turcica.

Dr. J. G. Curtis referred to a case that came under his observation while house surgeon in Bellevue Hospital, in the service of Dr. Markoe. A man who had attempted to kill himself by using a small brass single-barrelled pistol, loaded with a leaden bullet, and firing it off while held in close proximity to his head, in the temporal region, was brought to the hospital without special symptoms, and the probe, cautiously used, gave no special information. It was thought that the bullet probably had not penetrated the skull. There were no cerebral symptoms whatever for about five days. In the meantime it was found out that he was suffering from chronic Bright's disease. On about the sixth day he had morbid impulses, and requested to be sent to a room where he could be alone. He was so sent, and on the next day he became suddenly comatose, and died within a few hours. The symptoms were such as to render diagnosis doubtful, in view of the condition of the kidneys. Autopsy revealed a bullet lodged in the right middle lobe of the cerebrum, with considerable softening of brain-tissue about it, and acute meningitis of the whole surface of the right cerebral hemisphere.

Dr. L. M. Yale referred to a case in which a young man shot himself accidentally with a small pistol. The peculiarity at first was the existence of a certain obscurity in mental action. The boy went about during the day, changed his collar because it was bloody, but did not appreciate that he had been shot. In the evening he visited some friends, who, noticing something peculiar in his manner, and seeing blood on his collar, called a physician, who caused him to be put to bed. Head-symptoms came on gradually, with occasional lucid intervals, and during the latter the story of the shooting was gradually drawn out. He finally died comatose, and the ball was found, having caused a small abscess in the anterior part of the brain.

The President remarked that it was sometimes difficult to interpret the symptoms which followed gunshot-wound of the head. For example, in 1878 he was called to see, in consultation, a savings-bank director, who, through fear of arrest and prosecution for criminal misconduct, and being melancholic, attempted to destroy his life by discharging a pistol close to his right eye. The shot was made in the morning, and Dr. Sands saw him a few hours afterward, at which time the man seemed to be insensible. It was found that the ball had entered the right lower eyelid, and probably the eyeball. The eyesight was evidently destroyed, the pupil was dilated, but no considerable probing was done, and, although no aperture through the eyeball upon the distal side was discovered, it was believed that an opening existed, and that the ball had penetrated the skull and caused the cerebral symptoms. It was supposed that the man would soon die, but he survived, and gradually recovered; at times he seemed insensible, at other times incoherent; but there was something about the case that induced both the attending surgeon and Dr. Sands to suspect that the man was feigning disease. For it was said that during their absence he would get out of bed and walk about the room; and once he was found sitting very comfortably in an arm-chair, although he would not hold any conversation, and seemed stupid. Whether the ball penetrated the brain Dr. Sands did not know; he was led to believe that it did, because no severe inflammation of the eyeball followed the injury, as probably would have followed had the ball lodged there.

HERNIA CEREBRI.

Dr. Markoe referred to a case of fungus cerebri under his care, which was progressing exceedingly well under the plan of treatment which he was taught by his preceptor, the late Dr. Gurdon Buck, namely, liberal and frequent cauterization with nitrate of silver, and pressure by means of a compress, lead being preferable. The patient was a man æt. 20, and the fungus followed trephining. He supposed that it belonged to the class of cases in which the protrusion consisted of granulations from a healthy brain surface, and these cases could be treated satisfactorily by the method indicated. There was another class of cases in which the protrusion consisted of fungus from the sides of an abscess, and which ultimately and uniformly destroyed the life of the patient.

The solid stick of nitrate of silver was applied directly to the tissue and into it, and a mass as large as half a silver dollar could be melted away daily.

The opening in the dura mater was very small, and the protrusion occurred ten or twelve days after the operation, which was done to remove a small piece of depressed bone that lacerated the dura. Just before the granulations began to appear, the young man had one epileptic seizure, but it had not been repeated.

Dr. Briddon suggested the elastic ligature in cases in which the fungus assumed the mushroom shape, with the view of avoiding hemorrhage.

Dr. Post referred to the difference in prognosis, as to whether the accident occurred in children or grown persons—the majority of children recovering, and fatal terminations being very common in adults.

AMPUTATION FOR GANGRENE.

Dr. J. C. Hutchison referred to a case of gangrene of the forearm in which amputation would be necessary, and asked with reference to performing the operation above or at the elbow-joint. The gangrene was due to embolism.

Dr. Post remarked that if sufficient sound material could be obtained to cover the stump he should amputate at the elbow-joint rather than go above. He thought that a more useful stump could be obtained in that way than by amputating through the shaft of the humerus.

Dr. Weir referred to a case in which he amputated at the elbow-joint, and the stump was very satisfactory. Pressure could be borne without pain.

Dr. Markoe remarked that he had amputated at the elbow-joint twice with satisfactory results. He should prefer the elbow-joint rather than go higher up, and believed that, so far as the adjustment of an artificial limb was concerned, the difficulties would be eventually overcome the same as they had been with reference to amputation at the knee-joint.

Dr. Post referred to an amputation at the elbow-joint which he did on a young infant on account of malignant disease, and the stump was beautiful and in every way satisfactory a year after the operation.

Dr. Briddon referred to a case of senile gangrene of the foot, in which a line of demarcation had formed at about the junction of the middle with the upper third of the leg. He thought there was pulsation in the popliteal artery. He proposed to amputate at the knee joint, although he regarded the line of demarcation as evidence that amputation might be made quite near to it with safety. He asked with reference to amputating at or below the knee-joint.

Dr. Mason referred to the case in which Dr. Sayre amputated at the knee joint, and in which the popliteal artery was plugged so that no hemorrhage could occur, no ligature was applied, and the patient recovered.

Dr. Markoe referred to Dr. Peters's case, already reported to the Society [see minutes for stated meeting, Feb. 24, 1880], in which the popliteal artery was plugged at the time amputation was performed. In waiting until the limb had almost tumbled off before operating, he thought Dr. Peters did wisely.

Dr. Weir regarded it important in this as well as senile gangrene to avoid all possible causes of inflammation. In other words, in senile gangrene, remove the limb at the line of demarcation, and in the other cases where the amputation is made higher up, and observe full antiseptic precautions for the same reason.

The Society then proceeded to the transaction of miscellaneous business.

The Blind in France number 31,631. Of these, 5,928 were born blind, and 25,653 lost their sight by accident or disease.

Correspondence.

"RELATIONS OF NERVE AND MUSCLE" —A REPLY.

To the Editor of The Medical Record.

Sir:—I regret that the criticism of Mr. W. C. McGeffert, A.B., on one of my recent articles, is not more to the point, and consequently that it is not more of a character to facilitate an arrival at the truth of the several matters at issue. As my silence in reference to it might be misconstrued, I trust I may hope for the insertion of the following response:

I am asked to explain, in accordance with my theory, "why, at the moment of death or on cessation of the nervous functions, there is not an immediate muscular contraction?" I have already anticipated this objection in an explanation of considerable length, in the Record of May 8, 1880. If your correspondent has not read this explanation, this omission shows how little pains he has taken to grasp the subject as I have presented it. If he has read it, and does not accept it, he would have done better to set about refuting it, than simply repeating the question.

As to "why the muscles of a decapitated frog," instead of being at once contracted, "will still actively respond to the stimulus of electricity," the subject will be found discussed in the article entitled "Electricity a Paralyzing Agent," in the Medical Record for Nov. 1, 1879. For a very high estimate of the powers of the spinal cord as an independent organ, see Prof. Kuss's Lectures (Duval Amory), p. 32. The spinal cord centres of the decapitated frog continue to restrain the "property of contractility" in the frog's muscles, and the terminal nerves within the muscles continue this *rôle* after the cessation of activity in the spinal centres, and even after the removal of the muscle from the body. It is by the microscopic filaments of nerves in the nuclei of muscle-cells of the ultimate fibrillæ that the work of the muscle is done. Electricity suspends the function of these microscopic nerve-filaments, setting the protoplasmic cells of the muscle free to contract. The injury of a pinch, the shock of a blow, or the corrosion of an acid, applied to a nerve-trunk, causes a paralyzing wave to reach the nerve-endings, and produces a similar contraction. The idea that such rude assaults upon microscopic nerve-tissue act as "a stimulus," increasing its activity instead of arresting it, is worthy rather of the pickaxe and crow-bar brigade than of the histologist.

Your correspondent announces himself as "simply a student of medicine." Well, as he pursues his studies, he will find that there is a "difference between dead men," and that, in death from certain causes and by certain modes, nerve-force lingers longer in its proper channels, and maintains its relation to the muscles longer than in others. For example, as a result of hyperæmia, the muscles "preserve longer than is usual, after death has occurred, their proper contractility" (M. Charcot).

It was quite unnecessary for Mr. McGeffert to remind me that the heart has its own nervous ganglia, and "does not depend alone on the cerebro-spinal system." How little this is to the point will appear when it is recalled that my allusion was to "the pulsations of the fœtal heart, *before the development* of a *nervous system or of nerves*."

The *pulmograde acalephe* is propelled through the water by "the rhythmical movements" of its muscular disk, which bear a close "resemblance to the rhythmical contractions of the heart of higher animals." Yet the extent of the diffusion of a nervous system in these animals is "so limited that it is impossible to imagine the whole contractile tissue of the disk to be influenced by it; and, moreover, portions of the disk entirely separated from the rest, and *not containing any portion of the nervous centres*, will continue their alternating contractions and relaxations, just like the heart of a cold-blooded animal taken out of the body" (Dr. Carpenter: "Compar. Phys.," p. 634).

Here are illustrations on the highest authority, proving that, in the higher and lower forms of animal life, muscular contractile power is independent of any stimulus from the nervous system. Why should it be thought necessary to invoke this supplementary (purely hypothetical) stimulus in aid of the muscle, seeing, as Todd and Bowman state, muscular tissue is exquisitely organized for the production of its proper force, and "it is contrary to all analogy for one tissue to confer vital properties on another"? Where, in short, is the proof that nerves ever do stimulate muscles to contract?

I have never asserted or implied that "relaxation is active and contraction passive." I hold that, when a muscle is cut off from the influence of the will by paralysis of its nerve, the *muscle* itself is not "paralyzed." With the loss of voluntary power, the action of the motor nerve is weakened, but in the milder forms of paralysis it is still able to restrain the contractile power of the muscle. When contraction occurs, there is simply a deeper degree of nerve paralysis, which sets free the contractile power of the muscle. The justification of this view of the case is to be found in the records of pathology, which show that it is invariably the more serious or more protracted cases of nerve paralysis which are associated with muscular contraction.

In the case of the victim of a debauch, the motor nervous system is, of course, partially paralyzed by the narcotic effect of alcohol. When, in his subsequent tremulousness, "a stiff glass sets him to rights again," it acts as a temporary stimulant to his enfeebled nerves, restoring to them the balance of power over the muscles, and putting an end, for a time, to the incipient contractions of the latter. But, on the theory of the day, the tremors of the muscles are due to an excess of nerve-action, and the treatment ought to be of a kind to lessen the undue nervous excitement—that is, to remove the cause. Fortunately for our patients, the theory of the day is ignored in these and other cases, and the one here presented is wisely, though unwittingly, acted on.

Would my critic be surprised to learn that ligaturing a nerve-trunk arrests its power of conducting nerve-force? (Dr. Carpenter: "Hum. Phys.," p. 354). That compression of a nerve also results in paralysis, he will find by a reference to Dr. Hammond's work on "Diseases of the Nervous System," p. 303 et seq.; Soelberg Wells's "Dis. of Eye," p. 636; Bastian, "Paral. Brain Dis.," pp. 9, 10; Bennett's "Clinical Lec.," p. 307; Watson's "Lectures," p. 368, and numerous other authorities. So that it is quite justifiable to hold that the cramps in the limbs of a parturient woman, knotting the muscles, are due to the arrest of nerve-force; the pressure on the pelvic nerves sending a paralyzing wave to the extremity. How such a condition should cause the increased generation and "discharge" of nerve-force wherewith to "stimulate" the knotted muscle, it is impossible to imagine.

Your correspondent writes: "No one will say that spasms and conditions [contractions ?] are caused by nervous activity." Now, that is precisely what people do say, and what the theory of the day teaches. Thus, Dr. W. B. Carpenter states that "convulsive diseases are dependent upon excessive activity of the nervous centres" ("Hum. Phys.," p. 846). This idea pervades all the literature of this subject. Certain conditions and drugs are said to "excite tetanus" (Ringer, etc.). The spasms of strychnia-poisoning are attributed (as Dr. Anstie states, solely in deference to the theory in vogue, and not at all on the merits of the facts) to "an excitation of the spinal centres." So long as it is held, with Dr. Pereira, that "the muscles receive from the nervous system a preternatural stimulus to action," so long will excessive muscular action be held to be caused by an increased stimulus. Dr. C. B. Radcliffe defines "the current view of the physiology of muscular motion" as "a view according to which the excess of muscular contraction is owing to a corresponding excess in the stimulation of a vital property of irritability in nerve and muscle. See his "Lectures on Epilepsy, Spasm," etc. (p. 239), a considerable portion of which is taken up in the refutation of this doctrine.

The term "irritation," when used in this connection, is evidently synonymous with exalted action, because, when nerve-tissue is "irritated," if any modification in its action is produced at all, there must be either a lowering or an increase in its molecular activity. If the activity of the nerve be lowered, the tendency is to paralysis, and the "preternatural stimulus" on which muscular contraction is said to depend will be lacking. In order that such a stimulus be forthcoming, so as to produce spasm or rigidity, there must be an increase of nervous action. There is no other alternative; for nerve-action is either at, below, or above its normal standard of activity.

Now, my contention was that, if the current theory of the production of spasm were true, the remarkable success of stimulants in obviating that state is inexplicable and the use of these agents at all, under the circumstances, would be hazardous, or fatal. My critic, in order to justify the treatment, abandons the theory he set out to champion; and, unable to prove that in functional disturbances of a paralytic kind, or that amid atrophy, degeneration, and disintegration of nerve-tissue, there is a possibility of increased nerve-action, he shuts his eyes to the "breach in the old theory," admits "a depraved condition" as the cause of the spasms, and triumphantly exclaims: "What is more reasonable than to give stimulants?"

The following quotation from Dr. C. B. Radcliffe, F.R.S., is here in point. He says: "My impression is that the cases of paraplegia in which spasm or convulsion of the legs is a marked phenomena, are those in which the disease has the effect of preventing the legs from receiving the nervous influence which they ought to receive continually from the great nerve-centres of the head and neck; that in fact this increased disposition to muscular contraction in these cases is analagous to that which is manifested in the hind legs of a frog or rabbit after the spinal cord has been cut across by a knife" ("Lectures," p. 235). He is here referring to the experiment of Dr. Brown-Séquard, mentioned by me on p. 483 of the Record.

THE ACTION OF ACONITE.

I have sought to explain the action of aconite by its paralyzing effect on the vaso-motor nerves, as a result of which the arterial muscle, finding its contractile power no longer restrained, closes in upon itself, excluding blood-supply and curing congestion. Mr. McGeffert quotes Dr. Ringer, rather disingenuously, however, in order to disprove this theory. Dr. Ringer says, "*so far as we may draw a conclusion from the scanty experimental evidence, it appears that* aconite does not affect the vaso-motor centre or nerves, and therefore the lessened arterial pressure it induces is due to its action on the heart." My critic omits the words here placed in italics, which materially modify the force of the opinion expressed.

Dr. Ringer, however, admits that "very diverse statements are made concerning its action on the nervous system." He even adduces evidence that it acts on the peripheral nerves, as shown by "the tingling and numbness" it occasions in the extremities; and that it acts also on the vaso-motor nerves, by "the visible effects" of its internal administration on inflamed tonsils, in which "the large, livid, red, glazed and dry" condition rapidly improves. This must be due to its local effect on the dilated vessels of the part, exercised through the vaso-motor nerves which control the calibre of these tubes, since it cannot be supposed that a sufficient degree of prostration of the heart's action as would be required to produce so speedy a cessation of the hyperæmia could be induced without alarming consequences to general innervation. And as a matter of fact, no material depression is necessarily produced on the heart in the cure of congestive states by aconite. That aconite does depress the heart's action, through its local vaso-motor nerves and intercardiac vessels, and probably also through the proper motor ganglia of the heart, is of course fully conceded.

How much more reasonable is the explanation given above than the wild hypotheses to which the theory of the day conducts its adherents. For example, Dr. Ringer alleges (of a profound paralyzer like aconite) that it sometimes "*excites* irregular heart action!" He also quotes certain authorities who assert that aconite "stimulates the inhibitory centre of the pneumogastric," and then paralyzes the terminations of this nerve. Now, there must be something radically wrong in a theory which necessitates such absurd influences, which, deprived of the glamour of a *quasi* authority, with which they appear invested, would be received with becoming distrust and incredulity, instead of tacit acquiescence, by the great body of the profession.

Dr. Fothergill holds that aconite "paralyzes the vaso-motor nerves," but, as according to the theory of the day, the function of these nerves is to *stimulate* the arterial muscles to *contract* (Dr. Brown-Séquard, "Lec.," p. 205), and vaso-motor paralysis is attended by vascular dilatation, he is driven to the conclusion that aconite "increases the capacity of the vascular system, and by this means drains the blood away from the inflamed organ;" in fact, this drug "bleeds the patient into his own vessels" (Dr. Ringer, "Ther.," p. 399). This would be a very dangerous process, and if it were really to occur, so far from proving curative, would be simply transferring the hyperæmia from one organ to another.

One way, and perhaps the best, to arrive at a knowledge of the action of aconite is to study typical cases of poisoning by that drug. Such a case is reported by Dr. Henry Thompson, of the Middlesex Hospital, in the *British Medical Journal* for November, 1872: "When admitted, the patient was in a state of extreme collapse," having swallowed one ounce of Fleming's tincture of aconite half an hour previously. His face was dusky and the skin cold and clammy. Amid general symptoms of paralysis "the heart was acting most tumultuously and in a churning manner, the systole and diastole remaining inseparable to the ear." After death "all the cavities of the heart contained black fluid blood, and on the right side were some loose black clots."

The "clutching at the throat," so often present in poisoning by aconite, is doubtless due to the sense of suffocation, arising from gradual arrest of circulation in the lungs, owing to contraction of the pulmonary arterioles. As a consequence the right ventricle becomes distended with blood, and is so found in death. The distention, also, of the left ventricle, in the case just referred to, points equally to obstructed circulation in the peripheral arteries, and hence the paleness, coldness, and lividity of the skin and extremities.

Dr. Fothergill says of aconite poisoning in the rabbit, "if the dose be large the heart is still found to have been *contracting strongly*, and after death it is found in systole. If the dose be smaller, and the act of dying is more prolonged, *then the heart fails too*, and is found in diastole" ("Antag. of Ther. Agents," p. 93). The fact of the "tumultuous" action of the heart, of its "contracting strongly" and remaining in systole in death, from *a large dose* of the poison, shows that the heart *muscle* is not "paralyzed." Here the cardiac ganglia, which expand the heart (as the antagonists of its muscle), succumb early, from the large dose, before time has been afforded for peripheral vascular contraction and arrest of circulation. On the contrary, this peripheral blood stasis occurs from the smaller dose, "where the act of dying is more prolonged," and the damming back of the blood in the great vessels and heart causes the mechanical arrest of the latter in diastole. The subsequent passing of the heart into rigor mortis is additional evidence that the cardiac muscle had not lost its "property of contractility."

When electricity fails to produce contractions in the heart after death by a paralyzing agent, it is because the motor nerves of the heart are already so deeply paralyzed that the paralysis of electricity can produce no further effect in setting free the contractile power of this muscle. So long as there is any nervous restraint maintained over a muscle, electricity can always produce a contraction. When nerve-force finally ceases, the power of electricity over the muscle is also at an end, proving that this agent is, in itself, no stimulant to muscle.

I hope the newness and abstruseness of the subject will excuse the length of this reply. I must ask to deal with facial paralysis (in reference to which I am also challenged), in a subsequent paper, in which I trust to be able, from authentic facts, to satisfy the candid reader that the real phenomena of this disease are fully explained and are entirely in accord with the theory I have ventured to advocate, to which the facts of facial paralysis lend a strong confirmation. Yours respectfully,

Thomas W. Poole, M.D.

Lindsay, Ont., June, 1880.

(We regret to state that the publication of this interesting letter has been delayed until the present, on account of the crowded condition of our colums. —Ed.)

The Needy Widow of a Physician, having just lost her babe, desires a position as wet-nurse. It is perhaps unnecessary to ask any of our readers to help her in obtaining such a situation. Applications may be made through Dr. A. H. Smith or Dr. O. B. Douglas, 22 East Forty-second street, New York. Dr. Smith says he can vouch for her in every particular, and very properly adds that "it is a case which should interest every physician."

An International Veterinary Congress.—A national congress of veterinarians was held on the 8th of July, at Cureghemles, Bruxelles, to celebrate the fiftieth anniversary of national independence. Many prominent veterinarians from various parts of Europe were present. The congress lasted three days. Among the principal questions discussed were: Veterinary Deontology, The Inspection of Alimentary Animal Products, The Legislation of Redhibitory Vices (Veterinary Jurisprudence), The Organization of the Civil Veterinary Service.

Original Lectures.

A CLINICAL LECTURE.

By CORNELIUS R. AGNEW, M.D.,

CLINICAL PROFESSOR OF DISEASES OF THE EYE AND EAR, IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Case I.—Rupture of the Membrana Tympani.

Gentlemen:—Our first patient is Mr. Lynch, twenty-four years of age, who, three weeks ago, while "scuffling with a friend," received a "slight" blow over the right ear, with the palm of the hand. He felt at the time a ringing sensation in the head, and could hear very little with that ear. He had been deaf in the left ear nearly his whole lifetime, and he says the deafness was the result of catarrhal fever with whooping-cough. His right ear, during the three or four days that followed the blow over it, grew worse; hearing then improved a little, but since that time it has remained about the same, getting no better. After the accident he syringed his ear with warm water, which made it feel worse.

This watch which I hold should be heard to tick at a distance of forty-eight inches from the ear—that is, if the ear be in a normal condition. In making this test, it is better to begin at a distance, and bring the watch gradually nearer the head. It is also proper to have the eyes closed, so that you may concentrate the test upon this one sense. The senses are so related, the mentality of the senses is so complex, one sense aiding the other, that it is proper to shut off the sight. This is particularly true in the case of children. They imagine you want a certain answer, they see the watch and associate it with a certain ticking sound, and give you an affirmative answer, whether they hear it or not. They will do this after having seen the watch, even if you place it beneath your clothing, so that it cannot be heard at all. What is true of children is true, with some allowance, of older persons. The ticking of a watch is heard by our patient at a distance of six inches from the head, while the distance at which it should be heard is forty-eight inches. So, in recording the hearing distance of the right ear of this patient, we would write, H. D. R. $\frac{6}{48}$. The hearing of the normal ear would be written, H. D. $\frac{48}{48}$. Now we will test the other side, having our patient close his eyes and also his right ear. The watch, as you see is brought up so as to be in contact with the head, without the patient being able to hear it tick. He can hear the snapping of the finger-nails at a distance of two inches from the head, on the left side.

I wish now to have two gentlemen from the class examine this patient's ear, with Dr. Webster, by means of artificial light, and see what they have to report. The case is an interesting one, and one from which we may, I think, get some useful lessons in practice. Here we have one of Politzer's plates, giving us a view of the drum-head, as you look down upon it through the external auditory canal. This ridge running downward and backward toward the centre of the membrane, is the long process of the malleus. This cone-like reflection, which you see represented here, projecting from the end of the handle toward the periphery of the drum-membrane, is what is called the "light spot," and in the normal ear should have a distinct conical shape. Deviations in the shape of light spots are always noted by careful observers; they say "cone broken," or that it is "in position," or light spot "lighter," light spot "darker," light spot "diffused," light spot "small," or any qualification which will describe the shape or character of the light spot. When you look down upon the natural drum-head of a man at his time of life, you should expect to see the surface slightly inclined toward the anterior wall of the auditory canal, and resembling somewhat in tint gold-beater's skin. Over the malleus and at the periphery there may be a slight increase in the color, due to minute blood-vessels. These blood-vessels are seldom conspicuous enough to be seen separately in the normal drum-head. Sometimes, however, small vessels may be distinctly seen, but not extending upon the membrane itself. No obvious vascularity is normal, and in that respect the drum-head resembles the cornea. But now, when we look into this man's right ear, instead of finding this ridge running from the periphery of the drum-membrane, with a triangular light spot extending from its apex, you see a red surface, and that red surface is irregular. It is obviously the surface of the drum-head, but it is changed in appearance. The surface is red, and just here, behind the handle of the malleus, you will see a linear whitish surface in the midst of a red swelling, and it is very probable that this is a wound which was caused by the blow over the opening of the external auditory canal. We examined this patient in the other room, and we concluded that, at the time of the blow, the air was forced in through the external auditory canal with such violence as to have ruptured or torn the drum-head; and the redness which we find is due to traumatic inflammation. We have then a case of rupture of the membrana tympani of the right ear, from a blow, a thing which not infrequently occurs.

We will now speak of its treatment. When I asked the patient what he had done for his ear, he replied that he syringed it out with warm water soon after the accident. I then asked him if he had done it in accordance with the advice of any physician. He said no, that he did it on his own responsibility. My care in ascertaining this was because I did not wish, in my remarks, to cast any reflections upon treatment recommended by his physician, if he had any; for a medical man is always entitled to such doubts as may exist, and there are varieties of judgment. But, if the patient presumed to syringe his ear with warm water after the blow without professional advice, then we are at liberty openly to criticise the procedure as keenly as we like. He says that he syringed his ear with warm water after the blow. I do not think a much worse thing could have been done. I emphasize this procedure in order to condemn it. If I had been called in to see this patient immediately after the injury, and had been sure that rupture of the drum-head existed, I would have been careful not to introduce any substance whatever into the external auditory canal; such for instance as almond oil and the various other "drops" used for ears. Water poured, or thrown into the ear under such circumstances, might find its way into the drum-cavity, and there it would be a foreign substance. You see this remarkably in cases where the ear-douche is used. Many cases of suppurative otitis are due to such an occurrence. Water in the ear, even of a proper temperature, may lead to inflammation and abscess, and hence one of the objections to the use of Thudichum's douche, or any of the other forms of douches. Water is very irritating when in the middle ear, and if there be a rupture of the drum-membrane, when water is thrown in through the external auditory canal by means of a syringe, it will find its way into the middle ear and so do harm. This does not hold true in all cases of suppuration of the drum-cavity. The indication is to leave the edges of the wound in coaptation, unirritated by any foreign substance. There is no tendency to gape in a wound of this kind. On the contrary, there is a tendency to heal at once. You may demonstrate the existence of a perforation by means of having air whistle through under the pressure of Politzer's inflator, and yet find in the course of twenty-four hours afterward that healing has taken place and the aperture has closed. The proper thing is, then, to put a little cotton into the external canal loosely. Do not make a wad and stuff it into the canal; for, if you do, you will get up a certain amount of hyperæmia of the dermoid tissues, which help to feed the coming congestion of the drum-head. Instead of doing what is commonly done—taking a wad of cotton and thrusting it into the external auditory canal—take a small flock of cotton and lay it loosely in the canal, carrying it in just behind the tragus, so as to sift the air and keep off cold gusts of wind. You not only want to keep out such substances as water, but you wish to keep out cold air. Having done this, put the patient in a condition to use the organ of hearing just as little as possible, so as to give the wound a chance to heal. I do not think it would be good for such a patient to go to a concert, or to engage in an animated discussion, or be exposed to the noises of the streets. The organ should be allowed to rest, and should be watched. He will have some sensation of dulness in the ear, some sensation of deafness, some sensation of irritation, possibly pain, or, possibly some bleeding; if so, don't wash the blood out, but let it remain. If some of it should dry upon the surface of the drum-head, it will make a scab, and there is nothing better than a scab to protect it. If the drum-head is not much swollen, and is not, as we express it, angry-looking, let it alone and it will heal, probably, in the course of twenty-four or thirty-six hours. Now, suppose pain does come on, the drum-membrane looking red and angry, and the dermoid textures of the canal participating in the swelling, what would you do then? Here is another one of Politzer's plates, showing the external auditory canal, where one-half of the drum-membrane has been carried away, so that you may look into the auditory canal and cavity of the drum. Suppose that swelling has taken place, and the skin lining the external auditory canal has swollen so that you see less of the area of the drum than normal, what would you infer? That the process is going beyond what is normal and tending to healing, and is that of inflammation. Having observed this, the next step is to take blood from as near the seat of injury as possible; and, in order to do that, I would recommend that a leech be applied just within the external auditory canal, half an inch perhaps, at the base of the tragus. The way to apply the leech is as follows: take a little mass of absorbent cotton, and gently pack the external auditory canal with it, without inflicting any pain, and be sure that you leave the base of the tragus uncovered, for that is the point to which the leech is to be applied. Then take a cambric needle, or some other sharp-pointed instrument, and scratch the skin where you expect the leech to take hold, and then, with a leech-tube, apply the leech, letting it lay hold at the base of the tragus. Allow the leech to fill, and after it has dropped off take a large basin, or bowl, of hot water, and, having protected the shoulders of your patient, foment the part with a sponge dipped in the hot water, and so encourage bleeding from the bite for an hour or an hour and a half. The cotton prevents the blood from flowing into the external auditory canal, coagulating, and becoming a source of irritation. When the leech-bite does not stop bleeding, you may apply some styptic, as, for example, the persulphate of iron, upon cotton.

Having extracted blood in this way, you should give your patient a few hours of rest, and see whether this local depletion may not have accomplished the purpose desired.

If you have applied the leech in the afternoon, and there is still pain after free bleeding, it would be well to give an anodyne, perhaps eight or ten minims of Magendie's solution of morphia, as the case may be, and keep the organ awhile in a state of quiescence by placing over it a large bat of raw cotton. If, upon the following day, pain still continues, then you must begin to apply warm water to the external auditory canal, for by this time the edges of the wound will be so swollen that the water cannot get into the middle ear. The best way is not to throw it in with a syringe, but to pour it in from a spoon or sponge. By this time, as I have said, the wound will have healed, or its lips will be so swollen as to prevent the water from entering the middle ear. The leeching may have to be repeated. These are the simple rules to be followed in such a case of injury to the drum-membrane. Now, there was one test which I did not wish to apply here before the gentlemen were asked to see the case in the lighted room, and that is the test by the use of the Politzer bag.

I have here Politzer's inflator, which is simply a rubber air-bag, with a valve at its base for the introduction of air; and attached to this is a long black rubber tube, on the end of which is a hard rubber nozzle which fits the nostril. In order to use it, your patient is to take about a teaspoonful of water in his mouth, and hold it there until you tell him to swallow. The hard rubber nozzle is now introduced into the nose, and both nostrils firmly squeezed about it; then you tell your patient to swallow, and the moment you see the larynx move, squeeze the air-bag, which will force a column of air through the Eustachian tube. If there be a perforation of the drum-membrane, the air may be distinctly felt, passing out through the perforation, and a whistling noise will be heard. By this means I find that our patient has a perforation of the drum-membrane of the left ear, but none of the right ear. The perforation exists in the ear where the trouble has been for a long time. If we now had, as I have no doubt there has been, a perforation of the drum-membrane of the right ear, an experiment such as I have just tried would have given the sign of perforation. I would not have used the Politzer, had I been called in at the time of the accident, for it might have aggravated the trouble; but now, there is a sinking of the drum-head, and an inflation will elevate it and stretch any adhesions that may have formed. There is another method of inflation, which is known as Valsalva's, which consists in closing the nostrils with the forefinger and thumb, and causing the patient to blow from his own lungs up through the Eustachian tubes. This plan is not often employed, for there is an arrest of the venous circulation and congestion produced, which is unfavorable. We much prefer to employ Politzer's method, which does not increase the inflammation.

Case II.—Stillicidium lachrymarum.

Our next patient is a colored woman, who has been troubled with a watery eye for about a year. It is the left one, and the tears run over the edge of the lid whenever she looks down. There is no inflammation of the eye; in fact, nothing abnormal-looking about the upper or lower lid: but there is this constant stillicidium. There is evidently some obstruction to the nasal duct, and it should be probed. Our patient requests that this operation of probing should be done in her case under the influence of ether. The operation is so trifling a one, and the amount of pain so little, that I do not feel justified in complying with her request. (Exit patient.) I would be very sorry to give an anæsthetic under such circumstances.

Case III.—Injury of the cornea by a foreign body.

Our next patient is a gentleman who, one week ago to-morrow, received an injury to the cornea of his left eye from a foreign body. Dr. Webster tells us that yesterday he removed a foreign body from this patient's eye. His eye now looks red. The blood-vessels, which are unduly filled, are located near the inner canthus of the eye, in the conjunctival tissue. By looking sidewise at the eye we are enabled to tell, even with very little experience, whether the deep or the superficial vessels are the ones which are seen most prominently. In this case you can see the vessels branch in the layer of tissue immediately under your eye. By taking a probe with a little cotton upon the end of it, and, having dipped it in water, touching the tissue in which the vessels run, you will find that you can push it from side to side. You should learn in the examination of all diseased conditions of the eye to determine exactly in what tissue the abnormal condition exists. You should turn over in your imagination the various layers of tissue, as you would the leaves of a book, and in this way after a while you will be able to tell at a glance whether the inflammation be superficial or deep. If you will look at the lower edge of the cornea, you will see a little grayish abrasion, and that is the place from which the foreign body was removed. Now, suppose a case were brought into your office such as this was yesterday. Is any gentleman here prepared to tell me how he would proceed to remove it? One suggests a magnet. That is very good. But suppose you have no magnet? I will tell you of a very good method—one not usually described in books. Take a little stick, place upon one end of it a small pledget of cotton, and, after having moistened this, brush it over the surface of the cornea at the point where the foreign body is, and it will very likely be caught in the fine meshes of the cotton. Having prepared such a probe, the eyelid is drawn up against the superciliary ridge and the eyeball kept from rolling. Then, seeing exactly where the foreign body lies, you quickly brush over the surface, so impinging the cotton against the surface as to cause the foreign body to have a tendency to rise into it. In this way you may remove all foreign bodies not deeply imbedded. If you do as is so often done, namely, pick at the foreign body with a cataract needle, you may not get it out, and by your picking you may cause a great deal of pain. So I would recommend you to follow the directions which I have just given, which will answer in all ordinary cases. Suppose, however, that the foreign body is so deeply imbedded that you cannot get it out by means already cited. You can then take a cataract needle or a Bowman's spud so flattened at the extremity that it may be passed under the foreign body and tend to lift it out. You must be exceedingly careful not to injure the cornea, for that will impair the vision. Suppose there is a little mass of steel imbedded in the cornea, and you can see that it has gone through the cornea, so that the point of the steel is in the anterior chamber, and when you try to remove it you see a little leakage of the aqueous humor, then what should you do? You must get something back of the foreign body, or it will fall into the anterior chamber. You can do this by means of a Beers knife and under the influence of an anæsthetic. The eyeball should be steadied with a pair of fixation forceps, and the knife placed about a line from the body and perpendicular to the cornea. It should be carried right through the cornea into the anterior chamber, and then the blade of the knife turned and the handle depressed, so as to bring the point of the knife out beyond the foreign body, thus preventing it from falling into the anterior chamber. Thus you have the foreign body lying held in the cornea. It lies spitted upon the knife. I think I have been enabled by this method of procedure to pick out more than one foreign body and save the patient's eye.

Now, I do not think that eye-stones are of any value in removing foreign bodies from the eye. The only way they act is this. They are disk-like masses which tend to pass over to the inner canthus of the eye and there to discharge themselves. The advantage that the eye-stone is supposed to have is that it elevates the lid and allows the tears to wash the foreign body off from the surface of the eye. That might be an advantage in cases where simply a cinder got behind the upper eyelid, but this means is of no value in cases where the foreign body is imbedded in the cornea. It is a very bungling method, and I never use it. Now this man here will get well in a few days, I think. I would recommend that he keep the eye quiet and protect it as well as possible. The only thing I would use in the way of a wash would be a little table-salt in a little warm water, say a teaspoonful to the pint.

Bogus Diplomas.—Dr. Julius Hoffman of this city has complained to the Board of Health that a neighboring doctor is not a regular physician and is not entitled to practise medicine, for the reason that he has never graduated from a medical college, but held a fraudulent diploma. The diploma, the doctor claimed, purports to have been issued by the Berlin University. To establish a complaint he has shown a letter from the faculty of that institution denying that the physician complained of had graduated therefrom. Dr. Hoffman charges that the diploma was made in Chicago and sold for $10 to the present holder. The Board has referred the matter to Inspector Day for investigation.

Another case, showing, perhaps, the results of bogus diploma-mills, has been reported at Bradford, Pa. A so-called physician of that town put too much morphine in his prescriptions, and a patient is alleged to have died in consequence. He, as well as a drug-clerk, were arrested for manslaughter. The "doctor" is said to be a graduate of a bogus Philadelphia medical college.

Brooklyn Board of Health.—The Board of Estimate has cut down the amount asked by the Health Department from $48,000 to $18,000, which is certainly a mistaken piece of economy.

Original Communications.

NERVE-STRETCHING.

By J. H. POOLEY, M.D.,

COLUMBUS, OHIO.

I SHALL begin this paper by narrating the case which first drew my attention especially to the subject. It is as follows:

Dominick Monett, æt. 30 years. He was born in Canada, of French parentage, and removed to this country when four years of age. He is a brickmaker by trade. Eight years ago he was first attacked with sciatica, and for four weeks he was confined to bed, with intense pain in the right thigh and leg, and any movement of the limb gave rise to excruciating agony.

About four years ago his limb began to trouble him again, and since that time he has been lame about half the time, but still working at his trade whenever he was able.

The condition of his disease was, he thought, influenced a good deal by the weather, being worse in damp, cold weather, better in warm and clear weather. During the interval between his first seizure, eight years ago, and the present attack, he has been subject to sharp pain, with cramping sensation in the sciatic region, whenever he made a misstep or twisted his limb at all violently. These would last for several minutes, during which he would walk lame.

In September, 1879, he was compelled to stop work entirely. In February, 1880, he entered St. Francis' Hospital, Columbus, Ohio, and came under my care.

He had the ordinary symptoms of sciatica—pain along the course of the nerve, tender-points—puncta dolorosa—over the sciatic notch, the head of the fibula, and outer side of the dorsum of the foot. There was some wasting of the limb, with occasional spasmodic twitchings and considerable. paresis of motion; ordinary sensibility did not seem to be interfered with. No electrical tests were made. He was unable to walk except with crutches, and could only sit for a short time. He was easiest when lying on his side, with the affected limb drawn up. His pain was worse at night, being so severe as to deprive him of sleep, except with full doses of some opiate.

His general condition was remarkably good for a man who had suffered so much and so long.

For about three months a fair trial was given to all known methods of treatment, except the electrical, which, he said, had been tried before he came to the hospital, without any result—turpentine, purgatives, iodide of potassium, alkalies, quinine in large and small doses, cimicifuga, arsenic, etc.; hypodermic injections of morphia, atropia, chloroform, and ether; liniments of aconite, etc., blistering, and finally the actual cautery. Occasionally it would seem as though the right thing had at last been found, but the painful symptoms would soon return, and latterly with increasing severity. Finally, it was decided to stretch the sciatic nerve, and on May 12th I performed the operation. An incision about five inches in length was made just below the gluteal region, on the inner side of the long head of the biceps, and the nerve at once exposed without the least trouble, almost without dissection, and with the loss of only a few drops of blood.

The nerve seemed to be a little hyperæmic, but of this we could not be certain. It was not bound down nor adherent to the tissues around it. It was lifted out of its bed and forcibly stretched from both ends, so as to slightly lift the patient's foot from the table. During this process very distinct twitching of the muscles of the leg was noticed by one of the assistants.

A large-sized drainage-tube was introduced into the deeper part of the wound, which was then closed with sutures. Antiseptic precautions were carefully avoided.

May 13th.—The patient says although the wound feels very sore and pains him a good deal, the old shooting-pains have disappeared. He slept tolerably well last night. There is a spot of very marked hyperæsthesia along the outer surface of the leg, extending from the upper third to within three inches of the ankle; this spot is quite sharply circumscribed. There is no anæsthesia anywhere. The muscular paresis is rather increased; the limb, though easy when lying still, is painful on any motion.

From this time improvement was continuous and satisfactory. The circumscribed hyperæsthesia disappeared in a few days; pain ceased entirely; motion was gradually restored. In two weeks he sat up a little each day. The drainage-tube was removed in one week, and the wound dressed with adhesive strips and roller; there was scarcely any discharge from first to last, indeed the drainage-tube seems to have been quite a superfluous appliance.

By the end of the month he was well and up, pain gone, wound healed, still some weakness of the limb, but this is improving daily. He says he wishes he had had the operation performed three months before.

Nerve-stretching is not a very new procedure, having first been brought before the profession in 1872, by cases published in that year by Von Nussbaum and Billroth.

In 1877, Dr. Paul Vogt, Professor of Surgery in the University of Greifswald, published a small volume of eighty pages with the title "Die Nerven Dehnung als Operation in der Chirurgischen Praxis"—Nerve-stretching as an Operation in Practical Surgery. One chapter of this monograph is devoted by the author to the collection of all the recorded cases up to date. I do not undertake to say how complete this collection is—however, we are in the habit of giving the Germans credit for great thoroughness in such matters; suffice it to say, it only includes twelve examples of the operation, to which the learned professor adds three more of his own, all undertaken for the cure of tetanus, and in two of which the patients recovered.

Considering the gratifying measure of success which has followed the operation, we cannot help feeling surprised at the small number of recorded cases. I shall only be able to little more than double the list of Professor Vogt.

This arises in part, no doubt, from the three following circumstances: 1st. Cases demanding the operation are not very numerous. 2d. The indications for its performance are not as yet very well defined. 3d. No doubt many unsuccessful cases have not been recorded.

I will first present a résumé of such cases as I have been able to find, and then make such general remarks on the subject as they may suggest.

To begin with Professor Vogt's list, already referred to, they are:

1. Billroth (operation, 1869; published in 1872). Laying bare the sciatic nerve, and examining it with the finger. Nothing abnormal was detected. The spasm of the leg, for which the operation had been undertaken, completely ceased within three months of the operation.

2. Von Nussbaum (operation, 1872). This is the first published case. Laying bare and stretching the brachial plexus, on account of an intense neuralgia, of spasmodic contractions, and loss of sensation of the muscles of the arm. The operation was most completely successful.

3. Gärtner (1872). Laying bare and stretching the brachial plexus for a paralysis of thirty-four years standing. The arm was greatly wasted and the fingers contracted. Relief. Death in fifteen days.

4. Patruban (1872). Laying bare and stretching of the sciatic nerve for sciatica. Great amelioration.

5. Vogt (1874). Laying bare and stretching of the ulnar nerve, for paralysis and contractions, in consequence of adhesions with the nerve. Cured.

6. Von Nussbaum (1875). Laying bare and stretching of the tibial and peroneal nerves in a case of reflex epilepsy. Complete cure.

7. Callender (1875). Laying bare and stretching of the median nerve in the stump of a forearm on account of neuralgia. Cured.

8. Von Nussbaum (1876). Laying bare and stretching of the sciatic and crural nerves of both sides for central disease. Paralysis of lower extremities with clonic spasms, following on a fall eleven years before. Spasm entirely cured.

9. Vogt (1876). Laying bare and stretching the brachial plexus in traumatic tetanus following extensive injury to the hand. Cured.

10. Kocher (1876). Laying bare and stretching of the tibial nerve for traumatic tetanus. Result not given.

11. Petersen (1876). Laying bare and stretching of the tibial nerve for neuralgia. Cured.

12. Vogt (1876). Laying bare and stretching of the inferior dental for neuralgia. Cured.

13, 14, and 15. These are three cases of Vogt's, all for tetanus, two of them reported cured.

I will now add the cases I have been able to collect. I make no pretensions to completeness, as I have no facilities for a thorough investigation of the journal literature, where alone the requisite information is to be found.

16. Prof. E. Andrews, of Chicago (May 15, 1876). Probably the first operation of the kind in this country. Stretching of both crural and sciatic nerves, for painful tonic spasms of the lower extremities, the result of injury. Very great relief.

17. Dr. Drake, of Canada (1876). Stretching of sciatic nerve for tetanus, the result of a wound in the foot. Great relief to the symptoms, death on the thirteenth day, from neglect of the nurse.

18. Mr. Verneuil at La Pitié (1876). For tetanus, do not know what nerve was stretched, nor anything of the details. Recovery.

19. Dr. Macfarlane, of Kilmarnock (1877). Stretching of sciatic nerve for sciatica. Antiseptic precautions. Immediate relief and complete cure.

20 and 21. Dr. John Chiene (1877.) In *The Practitioner* for May, 1877, reports two cases of sciatica cured by stretching the sciatic nerve.

22. Eben Watson (1877). Traumatic tetanus, from lacerated wound of finger. Median, ulnar, and musculo-spiral nerves stretched. Death in two days.

23. Same surgeon (1877). Similar operation for tetanus from laceration of hand. Death in thirteen days.—*Lancet.*

24. Dr. Thos. G. Morton, of Philadelphia (1877). Stretching of ulnar nerve for traumatic neuralgia. Complete relief.—*Am. Jour. Med. Science.*

25. Same surgeon (1877). Stretching of sciatic nerve for traumatic neuralgia of foot. No relief. Subsequent cure from excision of two inches of the external popliteal nerve. (Same journal.)

26. Baum (1878). Stretching of facial nerve at stylo-mastoid foramen, for severe convulsive twitchings of the muscles of the face. Cured.—*Berliner klinische Wochenschrift.*

27. Annandale (1878). Stretching of the spinal accessory nerve for spasmodic wry neck, without any beneficial effect on the disease. The nerve was subsequently divided with the result of effecting a complete cure.

28 and 29. Mr. Nankivell, of Chatham, England (1878). Two cases in which the median nerve was stretched for traumatic tetanus. Both resulted fatally.—*Lancet*, March 2, 1878.

30. Dr. Manle Richardson (1879). Stretching of sciatic nerve for sciatica. Cured.—*Lancet.*

31. Langenbeck (1879). Both sciatics and right crural stretched for the shooting pains of tabes dorsalis. Complete relief of pain, and great improvement in the ataxic symptoms.—*Berliner klinische Wochenschrift.*

32. Kocher (1879). Exposure and stretching of the supra-orbital nerve for neuralgia. Complete cure.—*Correspondenzblatt für Schweizer Aerzte*, No. 14.

33. Klin and Knie (1880). Brachial plexus stretched for tetanus from compound dislocation of the thumb. Amelioration of symptoms; death in two or three days. —*St. Petersburg medicinische Wochenschrift.*

34. Pooley (May 12, 1880). Stretching of sciatic nerve for sciatica. Cure. Reported in this paper.

35. Dr. T. C. Hoover, of Columbus, Ohio (May 25, 1880). Stretching of left sciatic for painful spasm of the limb, the result of injury many years before. Relief. The nerve was divided into three trunks or cords, two of equal size, the third scarcely one-fourth as large as the other two. This case will be reported in full by the operator.

*36. Date and all particulars unknown. Callender stretched the external popliteal in a case of infantile paralysis in a child, the operation was not followed by any material interference with sensation in the parts supplied by the nerve.

*37. Callender, no date, case similar to No. 7. Cured, patient remained well fourteen months afterward.

I may add here, that Dr. Edward Lawrie has stretched the ulnar nerve in thirty cases of anæsthetic leprosy. In every instance the operation was followed by benefit, so far as the area supplied by the nerve was concerned.—*Indian Medical Gazette*, Sept., 1878.

We have here only thirty-five cases of all kinds, exclusive of the leprosy cases, a small number from which to draw any safe or legitimate conclusions; but inasmuch as it is the largest number that has been so far collected, I will venture to make it the basis of a few remarks.

In no case does it appear that the operation was the cause of death, unless it be in Case 3, and with regard to this my information is too meagre to enable me to decide. In only two cases did it fail to afford some measure of relief: Case 25, Morton's, traumatic neuralgia of the foot, which certainly does not seem to have been a very suitable one for stretching of the sciatic.

---

* These were notices of cases I came across accidentally after paper was written.

In Mr. Annandale's case of spasmodic torticollis, No. 27, it failed, and subsequent neurotomy succeeded. This is all the more remarkable as neurotomy and neurectomy both have failed in this complaint. In a case of my own, neurotomy having been unsuccessfully performed by another surgeon, I succeeded in curing my patient by multiple myotomy. It is to be hoped that nerve-stretching may have a further trial in this singularly intractable affection.

We cannot help commenting on the fact that, beside the two new cases reported in this paper, the operation seems to have been done only three times in the United States. In the operations, as recorded in the foregoing table, we find that the following nerves have been stretched: the sciatic, sixteen times; the crural and the median, each five times; brachial plexus and ulnar, each four times; the tibial, three times; the musculo-spiral, twice; the supra-orbital, spinal accessory, facial, inferior dental, and peroneal, each once; making a total of forty-four nerves stretched in the thirty-five cases.

The operation has been performed for sciatica six times; for other neuralgias, seven times; for local convulsive affections, tonic or clonic, with or without pain, eight times; for traumatic tetanus, twelve times; for reflex epilepsy and the pains of locomotor ataxia, each once.

It will be a convenient and instructive method to take up each of these categories separately, and strive to appreciate the value and indications of the operation for each, before entering into any general remarks upon the *modus operandi* or other questions connected with the procedure of nerve-stretching.

In all the cases of neuralgia, except one, the operation has been beneficial, and in most of them the cure has been complete. In the exceptional case, No. 25, it seems very probable that if the nerve which was subsequently excised with success had been stretched in the first instance, instead of the sciatic, the result would have been favorable. The special form of neuralgia known as sciatica has yielded excellent results from nerve-stretching, which may now be regarded as a thoroughly recognized procedure in obstinate cases. Professional opinion seems to be steadily advancing in favor of the operation in other forms of neuralgia. Especially in the traumatic variety is it likely to prove useful, as here there are more generally found adhesions of the nerve to surrounding tissues which stretching may break up. In such cases it has been found not only to cure the pain, but also the wasting, shiny skin, and other trophic disturbances associated therewith. When we compare neurotony with the kindred operations of neurotomy and neurectomy, the result is decidedly favorable to the former, as it is applicable alike to sensory, motor, and mixed trunks, and is capable of effecting favorable changes in the central ganglia, which are almost entirely beyond the reach of the other operations. A critical synopsis of the various methods of treatment of facial neuralgia is given in "Schmidt's Jahrbücher," Bd. 184, No. 10, 1879, by Dr. Deahna, of Stuttgart, which concludes as follows: "Nerve-stretching has only been tried in a limited number of cases, but with invariable, immediate, and lasting good effect. Consequently it should be resorted to when treatment by electricity has been tried without success." Similar endorsement of the treatment may be found by other writers, as Blum, quoted in the *Lancet*, Callender, and Farrar, of Chicago, etc. So that from the clinical testimony before us, the authority of writers on the subject, and theoretical considerations, we are justified in believing that many hitherto intractable neuralgias will in future be found amenable to this operation. And it therefore becomes a necessity for all practical surgeons and physicians to become acquainted with it, that more numerous trials may settle it upon a firmer basis, and extend the sphere of its usefulness. And surely any one who has seen a really obstinate case of neuralgia will hail with pleasure so promising an expedient for its cure.

The triumph of nerve-stretching is little less marked in local convulsive affections than in pure neuralgias. These peculiar conditions, often brought about by injury, are, as every physician knows, extremely varied in their manifestations. The spasms of a clonic nature are often violent enough to deprive patients of sleep, and seriously interfere with health and comfort. The tonic contractions often produce complete disability, and entirely prevent motion. Pain, though not a constant symptom, may be present, either in a spontaneous form or only provoked by attempts at motion, which latter may be, as I have seen, terribly severe. In all the cases of this kind, except one, of spasmodic torticollis (No. 27) which our list presents, either a complete cure or very great amelioration was obtained. And it is in this class of cases that the most extensive operations have been resorted to—stretching of several nerves, and on both sides of the body—but no ill consequences have resulted to diminish the glory of the result. As in neuralgia, so here the testimony of clinical experience, so far as it has been accumulated, is an unequivocal endorsement of the operation.

In the twelve cases of traumatic tetanus for which the operation was done, seven of the patients died, four recovered, and in one the result is not stated. Although almost all the operators speak favorably, and some of them in strong terms, of the relief to symptoms following the operation, it cannot, on the whole, be said that nerve-stretching has demonstrated its value here as clearly as in the diseases already referred to. But in coming to a conclusion, many circumstances need to be taken into consideration. The disease is known to be one of very formidable mortality under all treatment. The nerve-stretching has been done in every case in conjunction with other and often very energetic treatment; so that, except in striking and immediate improvement, it has not always been possible to give honor where honor is due. There can be no doubt that, as the matter at present stands, a physician would be culpable who trusted to nerve-stretching alone in this disease, and I do not think that the cases where it has been done as an adjuvant to other treatment show any better average results than may be hoped for from the treatment by chloral hydrate and calabar bean, of which I confess myself a somewhat enthusiastic advocate.

In some peculiar cases, such as the following, which I quote from Mr. Callender, there could be no doubt of its propriety: "A child sustained a badly lacerated wound of the tissues at the back of the knee, and the external popliteal nerve was exposed and torn from its surroundings for an inch or more of its course. During the healing of the wound, this nerve was covered in by granulations, and was fixed by them to the parts around. As the child lay convalescing, the leg contracted upon the thigh, and, as we wished to avoid after-trouble from this cause, a stirrup was applied, and the leg was drawn straight by means of a weight in the usual way. The evening after this had been effected the child complained of pain in the knee, and the muscles of the leg repeatedly started. The next day stiffness, contraction, and spasm of the muscles of the extremity set in, and although the weight had been at once removed and the leg had been reflexed, these signs quickly infested the muscles of the trunk, well-marked tetanus was recognized, and the child soon after died."

I think every one will agree with Mr. Callender when he says: "I regret very much that the peroneal nerve was not exposed and stretched in this case."

Finally, if the operation is to be done in tetanus, it is obvious that it should be done at once, early in the case, before the spinal centre has been irretrievably involved in the reflected irritation.

In a well-marked case of reflex epilepsy, where no definite local cause, such as foreign body, contracted scar, etc., could be found, or, if found, should prove irremovable, nerve-stretching, if practicable, is clearly indicated.

The one case in which it was performed for the neuralgia of locomotor ataxia is very interesting and suggestive. That it should have benefited the neuralgia might have been expected, but the marked benefit to the ataxic symptoms which is reported is quite remarkable. In any case of severe neuralgia in this disease the operation should be repeated, and if it be found that in repeated cases the ataxic symptoms also yield, it may become a valuable resource in this most inveterate complaint. I find a mention, the barest, in one of the supplementary cases (marked *), which I accidentally came across since this paper was written, of the operation being done in a child for infantile paralysis, for severe contractions following it, I imagine. This may be another field of usefulness for nerve-stretching.

The *modus operandi* of nerve-stretching has not yet been satisfactorily settled.

I shall say nothing about it, for I have nothing new to offer, and merely to repeat what others have said is quite unnecessary when addressing the members of a learned profession.

Of the technique of the operation I have only to remark that it will, of course, vary somewhat in different cases, and may be safely enough left to the surgeon to settle for himself. The operation is of itself quite innocuous, no harm having ever followed it, as far as I know.

Listerites will be Listerites till the fashion changes, but I will point them to the fact that in one of the reported operations where antiseptic precautions, so-called, were observed, there was free suppuration, while in mine, where they were avoided, there was scarcely any.

THE CORNER IN OPIUM.—The rumor of a prospective corner in opium, to which we referred some weeks ago, is again being circulated. The New York Syndicate is said to have purchased more than half of the 2,000 or 2,500 chests which constitute this year's short crop, and the price is said to have gone up from $4 to $4.50. Our large drug dealers, however, do not seem to be much alarmed; there is a prospect that the "corner" may fail; and at any rate, it is not thought likely that the drug will be run up to any very high figure.

THE UNITED STATES PHARMACOPŒIA OF 1880.

THE METHOD OF CONSTRUCTING FORMULÆ IN PARTS BY WEIGHT, AND THE PHARMACOPŒIAL WEIGHTS AND MEASURES.

By OSCAR OLDBERG, PH.D.,
MEDICAL PURVEYOR U. S. MARINE HOSPITAL SERVICE.

THE Sixth Decennial Pharmacopœial Convention of the United States, by a close vote, adopted "parts by weight" as the mode of expressing the proportions between the several ingredients in the pharmacopœial working formulæ, and thus virtually abolished fluid measures. The writer opposed this change, which he believes was made without reasonable assurance that it will be acceptable to a majority of the pharmacists and physicians of the United States. There will be a grave irrelation between the new pharmacopœia and the prevailing method of writing prescriptions, unless, indeed, physicians will at once surrender our valuable, convenient, and rational fluid measures, and prescribe exclusively by weight—an expectation which will probably not be fulfilled. The arguments used in favor of the new method will here be reviewed:

1. Greater accuracy is claimed for weighing as against measuring, because temperature affects volume, and because undoubtedly we can approach theoretical precision more closely with a sensitive balance than with graduated volume measures.

But both of these theoretical objections to the use of measures, where accuracy is important, do not apply with any force in reference to pharmaceutical manipulations. In fact, a practical view of the question cannot fail to convince any unprejudiced mind that they are the merest trifles, and not worthy of consideration in this connection.

The temperature maintained in the dispensing pharmacy or in the laboratory is generally subject to a variation of but a few degrees' range. Nearly all the operations of weighing and measuring are carried on at a temperature between 60° and 80° F., and the utmost extremes possible are within 50° and 95° F. Water and alcohol make up the bulk of most of the liquids used, and, moreover, fairly represent the extremes of expansion by heat of the liquids measured in pharmacy. The following table, from Péclet's "Eléments de Physique" (see "Fowne's Chemistry"), gives the variable expansion of liquids by heat, and contains the extremes of variation *between the freezing and boiling point of water:*

Apparent dilatation in glass between 0° *and* 100°.

Water	$\frac{1}{22}$
Hydrochloric acid, sp. gr. 1·137	$\frac{1}{27}$
Nitric acid, sp. gr. 1·4	$\frac{1}{9}$
Sulphuric acid, sp. gr. 1·85	$\frac{1}{17}$
Ether	$\frac{1}{14}$
Olive oil	$\frac{1}{12}$
Alcohol	$\frac{1}{9}$
Mercury	$\frac{1}{64}$

The greatest expansion is shown in alcohol, and amounts to $\frac{1}{9}$ in 100 degrees, or $\frac{1}{900}$ of its volume for each degree of the centigrade scale! From 10 to 35° C. (50° to 95° F.) the extreme possible variation would be $\frac{25}{900}$, or 2·77 per cent., and from 16° to 27° C. (60·8° to 80·6° F.) it would amount to $\frac{11}{900}$, or 1·22 per cent.! This is the extreme limit of the liquid subject to the greatest expansion. The extreme expansion of water between 50° and 93° F. is less than one-half per cent. But what is the greatest *probable* variation of volume under the conditions affecting the ordinary operations of measuring in pharmacy? The writer does not believe that it exceeds, in any case, one per cent. But let us suppose it to be two per cent. Will any one seriously claim that a possible variation of two per cent. can produce any appreciable effect therapeutically—for that is, of course, the only question worth discussing? Who would be able to discern any difference between the medicinal activity of a tincture made of 10 ounces drug to 100 ounces menstruum and the medicinal activity of the same tincture diluted with one or two ounces more of the menstruum? I do not think it possible to distinguish between the two *in any way whatever*, and yet this is a fair statement of the maximum variability possible when liquids are measured instead of weighed.

Who would say that the same system which is so satisfactory in volumetric chemical analysis does not afford sufficiently accurate results in pharmacy? Practically, for pharmacal purposes, measuring is quite as satisfactory as weighing, provided reasonable care is exercised. *Without care, weighing is worse than measuring.* As soon as the equilibrium of the balance is destroyed and the scale goes down, how can it be known, except by guessing, what the excess is? It is *not* known. On the other hand, in pouring a liquid into a graduated glass measure, if an excess is added, it is plainly seen, and the operator knows at a glance whether or not the error is of sufficient magnitude to require correction. *With* ordinary care, the errors in measuring, and the liability to error, are too trifling to condemn the system, provided *accurately* graduated measures are employed. Even the concavity or convexity of the surfaces of liquids arising from capillary attraction in the process of measuring them, can readily be allowed for; and to reject fluid measures on their account is a refinement uncalled for in pharmacy, especially when we consider that ordinarily the operation of weighing does not insure any greater accuracy. *Dropping* is far from accurate; yet it is nearly as accurate as weighing when the quantity is very minute; and dropping is resorted to even by the warmest advocates of the exclusion of measures.

It is further argued that inaccurate and badly made graduates are on the market, and that therefore measures should be abandoned. But inaccurate weights are quite as common. Is it likely that pharmacists who make it their duty to verify their weights, will fail to verify their graduates also? No; those who do not verify their measures will not verify their weights and their scales. Accurate graduates and accurate weights are both readily obtained.

The argument (actually used in the Pharmacopœial Convention) that the copper and tin measures used in the laboratory are frequently dinged out of shape and thus rendered inaccurate, does not seem to require any reply.

2. It is claimed that "parts by weight" is applicable to any or all weight units.

This is a plausible, but valueless argument. Which would the practical pharmacist rather have—a formula giving the definite quantity to be used of each constituent in producing a fixed quantity of the final product adjusted to the probable wants of a large number of pharmacists, or a formula such as the one given for comp. syrup of the phosphates, on pp. 143, 144 of the "Report of the American Pharmaceutical Association on the Revision of the Pharmacopœia"? In using the former we can at once determine whether we want to make all of it, or half of it, or twice as much. In using the latter we find eighteen separate numbers given, representing parts by weight, the last one being 3,250 parts, representing the final product. What pharmacist wants 3,250 pounds, ounces, drachms, grains, or grams of that preparation? Not one in ten thousand. After trying in vain, then, to substitute any one of our weight units for the word "part," to arrive at a suitable amount of final product, we are obliged at last, in order to be able to use the formula constructed in parts by weight, to transpose it practically into the same kind of a working formula that we have in the present pharmacopœia, except that weights are substituted for measures, and the fraction or multiple required of the quantity of final product thus expressed is more likely to be complicated, unusual, or inconvenient, than simple.

It is said that a formula in parts by weight is more readily understood, for purposes of comparison, by pharmacists in different countries, where different systems of weights and measures are used, than a formula in troy or metric or other fixed units. Any supposed advantage on that score is not worth making any sacrifice for. The comparison can be made one way as well as another, and is convenient only when the final product, or the number of parts representing the latter, happens to be the same, or with the same system of weights and measures.

3. Greater clearness is attributed to formulæ in parts by weight, as compared with formulæ in definite quantities.

This claim is unwarranted unless the total (final) product be an even one hundred or one thousand parts, so as to make the percentage of active constituent at once apparent. But unless that percentage is expressed by a simple number, so as to be easily remembered, it is of no value. The physician principally needs to know or learn the *posological strength* of the drug and its preparations, and the percentage or proportional strength is of no consequence to him, except as a means of determining its posological strength. That the dose of liquids should be stated and known by measure and not by weight will be presently shown.

If the final product is one hundred or one thousand weight units, it does not matter whether these units are called parts, or ounces, or grains, or grams. The result is precisely the same so far as clearness and convenience are concerned.

4. The friends of parts by weight point to some of the leading pharmacopœias of the world for precedents.

When "parts by weight" was adopted in Germany, Sweden, and other countries, *fluid measures were not thereby abolished*, for they did not have any to abolish. Fluid measures were not sanctioned in pharmaceutical operations in those countries, and were used only in straining decoctions and infusions, and in selling common liquid drugs and preparations over the counter, without prescription. The adoption of "parts by weight" in those countries was, therefore, not the parallel of the adoption of that method in this country.

Because it is susceptible of demonstration that, at least theoretically, gravimetry is more nearly perfect in its results than volumetric methods, the continental European governments prescribed that all quantities in medicine, whether liquid or solid, must be determined by weight, and measuring was prohibited. With this mandatory law there could be no demand for graduated measures, and consequently no supply of them such as alone could afford the opportunity for a fair practical test of the volumetric system for general pharmaceutical purposes. If the pharmacists of the European continent, who thus never used fluid measures except unofficially or in a very crude way, could only obtain a thorough practical familiarity with their advantages and real practical accuracy, I believe that, had they the freedom we enjoy in America, they would not be slow to adopt them and to use them as freely as we do. It would have been wiser for us to expect them to adopt our exceedingly convenient and sensible system, than to incontinently abandon fluid measures for the sake of international uniformity.

European chemists, who surely may be credited with the most scrupulous accuracy, do employ fluid measures in quantitative analysis, their employment for that purpose not being forbidden.

5. Probably the weightiest reason for the adoption of parts by weight in the recent convention was the conviction that such action must inevitably lead to the adoption of the metric system.

This, I grant, is logical, and it is unnecessary for me to say that I greatly desire the adoption of the metric system, believing it to be the best, the most rational, labor-saving, convenient, and easy of all. But I am as earnestly convinced of the great value of fluid measures in medicine and pharmacy, as of the value of the metric system.

Many of the advocates of "parts by weight" in the convention informed the writer that they voted for that method chiefly because they wanted the metric system adopted, fearing that the open and unconditional adoption of the metric system could not be carried through the convention, or, if carried, would not meet with popular favor. They argued that a large number of pharmacists who are decidedly opposed to the adoption of the metric system would not oppose the adoption of "parts by weight" as a sort of compromise, because it is generally believed that the old system of weights (and measures) can be applied in using formulæ in parts by weight as conveniently as the metric system. The truth is that the metric system is the *only* one that can be *conveniently* used in that connection, and what will be the reception given by the great body of physicians and pharmacists to the method adopted will not be rightly appreciated until after the new pharmacopœia shall have been issued.

Many earnest friends of the metric system seem to think that volumetric methods are not consistent with it, and that if the metric system is adopted we should naturally dispense with fluid measures. This is a misunderstanding. We can very properly adopt the metric system, measures and all, as has been done in the marine hospital service. The writer, for one, would rather retain the old system of weights and measures, than adopt metric weights without the privilege of using metric measures also.

The real difficulty is that the majority of physicians and pharmacists do not yet sufficiently understand the question in all its bearings, are not prepared to decide it for themselves, and thus could not make their wishes felt in the Pharmacopœial Convention. That this radical change was in May last for the first time discussed in any large assembly of representative physicians and pharmacists cannot be successfully gainsaid. That it was *not discussed* in the Pharmacopœial Convention of 1870 is well known, and notwithstanding its adoption (on paper) by that convention the matter has not received general and careful attention since, because the Committee of Revision did not carry it out, and in ten years it was forgotten.

When the new pharmacopœia (1880) is issued, the question will be brought home to the professions in such a way that they cannot help taking due notice of it, and they will have an opportunity to subject the new system to a practical test extending over ten years, so that in 1890 we shall have an intelligent vote upon it, based on experience. The writer predicts that a thorough sober consideration of all the points involved will yet lead a large majority to the conclusion that the adoption of "parts by weight" and the abolition of fluid measures were mistakes. Among the points which did *not* receive consideration in connection with the change are these:

Medicines are prepared for the sick. A very large, if not the larger, number of medicines prescribed are liquids. Liquid medicines are of necessity administered to the sick by *teaspoonfuls, tablespoonfuls*, or some other convenient *measure*—never by *weight*. Hence the physician should know the dose by *measure.* To know doses by measure intelligently, he must have preparations the *strength* of which is determined *volumetrically.* He does not care to know how much of the active constituent there is in a certain *weight* of a fluid extract, or a tincture; but he wants to know how much there is in a certain *volume* of it, for between himself and the person who takes or administers the mixture, weighing is out of the question. If the formula itself does not furnish the information he wants, he must either resort to a tedious and often difficult arithmetical process to obtain it, or guess at it, or fall back upon a table already prepared for him.

Are the physicians ready to surrender the pharmacopœia? Or are they content to simply prescribe what drugs and preparations shall be officinal? If there are those who care so little for the pharmacopœia, this paper is of no interest to them. But the writer believes that physicians also should know and control the *strength* of the preparations, and desire to have the work so constructed as to be at once intelligible and readily consulted with reference to the amount of active matter in any given dose they may prescribe. Unless liquids are prescribed by volume in the official formulæ, and the amount of the final product of each formula determined by measure, the pharmacopœia will be practically useless to the physician.

The first thing thought of by the physician, when about to write his prescription is, I believe, how many teaspoonfuls or tablespoonfuls, do I want to have put up? After settling that point he constructs his prescription accordingly. But how is he to get a certain number of teaspoonsfuls if obliged to prescribe exclusively by weight? That it is *possible,* we grant; but it is difficult and awkward. Common sense teaches that the most *direct, convenient,* and *accurate* way to get at a certain quantity *by measure* is to *measure* it out—not to *weigh* it. How inconsistent to exclude measures on the ground that they are less accurate than weights, in the face of the fact that to prescribe *by weight* definite *volumes* of tinctures, syrups, spirit of nitrous ether, fluid extracts, etc., is practically impossible to be done with accuracy unless much more labor is given to the construction of the prescription than busy physicians can afford to bestow on that feature of it. To this difficulty must be added the fact that, with fluid measures abolished, doses must be learned over again with no convenient landmark at hand for the correction of possible errors.

To be consistent, medicines prepared in proportions by weight only should be both prescribed and administered by weight also. The physician is now invited to choose between two evils—he must either prescribe by weight, or practically ignore the pharmacopœia.

In a fruitless effort at perfect accuracy, the pharmacopœia has been removed from the physician's control, and handed over to the pharmacist, and there is now no connecting link between the preparation and prescribing of liquid medicines—unless physicians agree to abolish fluid measures, too, or the pharmacists readopt them.

The same common sense which dictates that liquid remedies are best *administered* by measure, taught the eminently practical English-speaking peoples to *prescribe* them by measure also, and finally to *prepare* them by the same rule, thus establishing harmony throughout. Continental Europe is behind England and America in this respect; but, for the sake of uniformity, we are now required to step back.

The report of the American Pharmaceutical Association on the revision of the pharmacopœia may be said to fairly represent what the new pharmacopœia is to be with reference to the statement of proportions in the working formulæ. The physician who can consult that work, and ascertain, in a reasonable space of time, the quantity of active constituent in a teaspoonful dose of either of the liquid preparations, must be an unusually good mathematician.

As to convenience, there is no comparison between weighing and measuring liquids. As a rule, to weigh them is a slow and awkward process. Even the best friends of "parts by weight" concede that to withdraw the receiver from under the percolator from time to time to ascertain by weighing when the percolation has proceeded far enough, would be too troublesome, and their remedy for it, as seriously recommended in the convention, was *to graduate the receiver, and then measure the weight required!*

Finally, the gentlemen by whose votes "parts by weight" was adopted, still seriously doubt the propriety of including fluid extracts under this rule, and these preparations were left to the discretion of the Committee of Revision. The writer is at a loss to find any tangible reason for determining the strength of fluid extracts volumetrically, which does not apply with equal force to all other liquid preparations; but if any good reason exists why exceptions should be made, the rule was hardly worthy of adoption.

The question is, however, settled for the next ten years to come, and it behooves us all to do our best to fairly try the adopted standard. Pharmacists should scrupulously carry out the requirements of the new pharmacopœia in all its details, so as to prepare themselves to say, in 1890, whether they will continue the exclusively gravimetric system, or readopt fluid measures. Physicians who wish to be in perfect harmony with the new pharmacopœia, will, of course, write their prescriptions exclusively by weight, making careful allowance for the practical bearings of the relation of weight to volume (especially in mixtures), in order to properly adjust the dose. Those who continue to prescribe by measure are warned that necessarily the preparations of the new pharmacopœia will not be identical in strength with those of the old, and that in some cases the difference will be so great as to require attention, so that a new posological table, adjusted to the new pharmacopœia, will be greatly desirable. Finally, the system of weights and measures to be used should be uniform, and adapted to the new order of things. As "the relationship between the weight and the measure of a given volume of any liquid preparation" will be a matter of concern, we want a system of weights and measures in which that relationship is at once expressed in the specific gravity. It is, in other words, inevitable, that to put our practice in harmony with the new pharmacopœia, we must adopt the metric system. Fortunately, there will be in the new pharmacopœia a "weight and volume table, to facilitate the use of parts by weight (or, of the decimal system) in compounding, prescribing, and dispensing medicines." (See the instructions of the Pharmacopœial Convention to the Committee of Revision and Publication.) There will also be a table showing the differences in strength between the preparations of the new pharmacopœia and those of the old. These two tables will, doubtless, be the most valuable part of the book to physicians.

Should, after ten years' trial, the physicians and pharmacists desire to continue the method of "parts by weight," the writer will completely change his mind. Should they, however, find that they would rather have fluid measures, and send delegates to the next pharmacopœial convention who will vote to readopt fluid measures, it is hoped that the failure of parts by weight may not be laid to the charge of the metric system. The metric system, so Americanized and simplified as to make it quite easy for any and every one to understand it, know it, and at once use it, would probably have proved far more acceptable to a majority of physicians and pharmacists than the adoption of parts by weight. The greatest bugbear in the way of the adoption of the metric system is, that the numerous *foreign words* and *prefixes* we must learn are troublesome. But this objection is easily disposed of. The metric system does not consist of these many words and prefixes, *which we do not need to adopt at all.* At the very utmost, we would have to learn *four* new units: two for weights, and two for measures. But, in fact, only two of these four are important. One is the GRAM, equal to about 15 grains, or ¼ drachm; and the other the (cubic centimeter, which, as suggested by Mr. Alfred B. Taylor, should be called a) FLUIGRAM, equal to about 15 minims, or ¼ fluid-drachm. For large quantities we might use the KILO and the LITER; but the only necessary units are the gram and the fluigram. The question really resolves itself into this: Is it too much or too difficult to remember that one gram is the fourth part of a drachm, and that the fluigram is the fourth part of a fluid-drachm, and to use these units accordingly? We would then have:

1 kilo equal to 1,000 grams,
1 liter equal to 1,000 fluigrams,

and

1 gram equal to ¼ drachm,
1 fluigram equal to ¼ fluid-drachm.

With the metric system thus Americanized, and *fluid measures retained in it,* we would be in perfect harmony with the rest of the civilized world, and greatly in advance in the practical convenience and accuracy with which we could compare the dose administered to the patient with the strength of the preparation as shown in the officinal formula.

CENTRAL KENTUCKY LUNATIC ASYLUM.—Dr. Geo. T. Erwin, formerly of Danville, Ky., has been appointed Assistant Physician to this institution.

NOTE ON THE ERRORS OF CLINICAL THERMOMETERS.

By LEONARD WALDO, S.D. (Harv.),

ASTRONOMER IN THE OBSERVATORY OF YALE COLLEGE.

I am in receipt of inquiries from members of the medical profession, which betray such ignorance regarding the amount of error to be expected in the clinical thermometers sold by the dealers, that it seems proper to indicate in a general way the errors actually found to exist. I do this with some reluctance, because it seems an injustice to makers who are already making more accurate instruments under the encouragement of our observatory; yet as there must some time elapse before certified thermometers will be in general use, and as, meanwhile, many temperature observations will be made which are important, I think there should be some warning given that, without specific knowledge to the contrary, the thermometers in general use are not to be relied upon within one-half degree Fahrenheit.

Of course I except from this statement those instruments which have a Kew certificate not more than six months old; and if the age of the thermometer could be ascertained to have been one or more years when it was verified, then the verification would hold good for a longer period.

Here, for example, are the corrections of two Casella thermometers of excellent construction:

Correction at	Casella, 37,199.		Casella, 37,200.	
	Kew Observatory, December, 1878.	Yale Observatory, June, 1880.	Kew Observatory, December, 1878.	Yale Observatory, June, 1880.
90°	−0.1°	−0.5°	−0.1°	−0.5°
95°	−0.1°	−0.5°	−0.1°	−0.5°
100°	−0.0°	−0.4°	−0.0°	−0.4°
105°	−0.0°	−0.4°	−0.1°	−0.5°
110°	+0.1°	−0.3°	−0.1°	−0.5°

which indicates, since the Yale comparisons were made with Kew standards, whose errors were independently found at Yale to be as they were stated to be at Kew, that the Casella clinical thermometers had increased their readings 0·4° in the eighteen months elapsing between the two comparisons. It is an accepted fact that mercurial thermometers, at the temperatures used in medicine, always increase their readings with age, and much more rapidly in the first few months after the tubes have been made than at any subsequent time.

It is very much to be desired, therefore, that the tubes to be used for thermometers should first be filled with mercury, and then laid aside for two years before they are finally graduated.

It has been suggested that the observatory not only verify thermometers, but that it receive the ungraduated thermometer-tubes, and after registering the numbers in them, seal them up in packages for the space of two years. That for such seasoned thermometers the observatory issue a certificate stating not only the usual scale of errors, but also that they were properly aged before graduation. Such thermometers would change their errors but slowly, and ought to command enough higher price to justify the dealers in the trouble taken.

As far as the observatory is concerned there is no objection to such a procedure.

To show the errors commonly existing in clinical thermometers, I have selected the readings of sixty-eight thermometers verified in June of this year. Since each thermometer had its errors determined at five points of its scale, 90°, 95°, 100°, 105°, 110°, (except a few which were graduated from 95° to 110°), we have about three hundred and twenty separate points upon whose errors we can base an estimate of the thermometers in general use. Seven different (and leading) makers, domestic and foreign, are represented in the thermometers used. An analysis of all the readings shows that—

19 per cent. of the readings are within 0.1° of the truth.
8 " " " " between 0.1° and 0.2° in error.
7 " " " " " 0.2° " 0.3° "
7 " " " " " 0.3° " 0.4° "
13 " " " " " 0.4° " 0.5° "
20 " " " " " 0.5° " 0.6° "
9 " " " " " 0.6° " 0.7° "
8 " " " " " 0.7° " 0.8° "
6 " " " " " 0.8° " 0.9° "
1 " " " " " 0.9° " 1.0° "
2 " " " " in error more than 1.0°.

Occasionally the observatory receives a thermometer which is evidently wrongly graduated by an even 5°, and this provokes the suspicion that there may be such sometimes sold.

It is not difficult to trace the causes of the discrepancies given above; one is the too early graduations of tubes before they are seasoned, and another is the use of a standard for graduation which has itself become too high in its readings with age. There is no direct way of determining the errors of clinical thermometers themselves, since neither the boiling nor the freezing points are indicated in their stems; and even the possession of a standard with which a thermometer is to be compared is not very helpful, unless the observer has the means of determining the fiducial points of the standard, and is perfectly sure of the errors of calibration. It is much better to send clinical thermometers to some recognized observatory and obtain an investigation of its errors. So firmly is this view rooted in the medical mind in England, that in 1879 some 3,400 clinical thermometers were verified at Kew alone.

It is now pretty generally known, at least among the New England members of the medical profession, that the new observatory of Yale College has undertaken to afford to physicians an accurate statement of the errors of clinical thermometers sent to the observatory for such a purpose. This work has but fairly commenced, yet that it will be an important public service is already abundantly shown by the hearty response made by the profession and the American thermometer makers to the inquiries instituted by the observatory Board regarding the expediency of such an establishment. It is in general after the plan of the Kew observatory in England, and a descriptive circular has been prepared for distribution.

Dr. Manley Emanuel, who resided in Philadelphia for ten years past, died at his residence, No. 1,324 Green street, that city, recently, aged eighty-six years. He was president of the Delaware County Medical Society for sixteen years in succession, and also of the Board of School Directors. In addition to these, he was at one time United States examining surgeon for pensioners, and a justice of the peace. He was graduated from St. George's Hospital, London, in 1816, and became a fellow of the Royal College of Surgeons.

Reports of Hospitals.

COOK COUNTY HOSPITAL, CHICAGO.

Notes of Practice and Treatment.

Case I.—*Uræmic Convulsions in Bright's Disease—Hypodermic Injections of Chloral.*

John McC., æt. 23, admitted to hospital under care of Dr. Bridge, April 9, 1880. The patient had been addicted to the use of alcoholic beverages, in quantities more than moderate for the past three or four years, but had always enjoyed good health. Three weeks before he caught a severe cold; the week following noticed the body was anasarcous; had slight dyspnœa; annoying pains in lumbar region; frequent micturition and headache.

When admitted the heart and lungs were normal. Urine, sp. gr. 1014; acid, abundantly albuminous, smoky and pale brown; tubular epithelium in granular condition, and casts in great quantity. Was given milk diet and the following:

℞. Auri et sodii chloridi......... gr. i.

M. et fl. pil. No. xxx. S.—One pill four times a day.

April 15th.—This a.m. had convulsions; recovered in five minutes, and soon had a second, more prolonged and characterized by nystagmus, frothing at mouth, biting of tongue, rigid neck, and slight opisthotonus.

At 10 a.m., another convulsion, in which the tonic stage was well marked; opisthotonus extreme, face and hands cyanotic. Convulsions to the number of ten or twelve followed in quick succession; consciousness was not restored between them.

Dr. B. arrived at 11.20 a.m., and at once administered chloroform, by inhalation, to control spasm.

At 12.05 he injected hypodermically 8 grs. chloral hydrate, in solution with water; 12.30 p.m., injected 8 grs. chloral; 1.10, is slightly conscious and answers questions; 2.00, injected 10 grs. chloral; 2.25, injected 5 grs. chloral; 3.00, injected 5 grs. chloral, which seemed to abort a threatened convulsion; 3.40, injected 5 grs. chloral; 4.10, injected 5 grs. chloral; 5.15, injected 5 grs. chloral; 7.30, patient was put in hot pack; 9.15, patient took by mouth ʒ i. ext. Jabor. fl.; 10.10, injected 5 grs. chloral. Is perspiring profusely. Drinks large quantities of water. Put on another hot blanket.

April 16th, a.m.—Feeling well; is quite talkative. Remembers little of the day previous.

℞. Ext. Jaborandi fl.
S.—ʒ ss. every three hours.

This quantity was taken for one day, then ʒ ss. three times a day was given until five ounces had been taken, the drug causing no derangement of digestion and producing only moderate diaphoresis. Pulv. Jalapæ comp. ʒ i. was given each night. Pills of chlor. of gold and sodium also continued till May 26th, when a careful examination of the urine showed no albumen, casts or epithelium; the œdema had disappeared, and patient, who had been rapidly regaining his health, was discharged.

The solution of chloral was of the strength of eighty grains to the ounce of water. The injections were made mostly in the arms and legs.

No phlegmons or abscesses formed at any of the points of introduction of the medicine. In all, fifty-six grains of chloral were injected under the skin.

Case II.—*Hypodermic Injections of Hydrate of Chloral for Delirium Tremens.*

John A., was admitted at 10 a.m., after suffering four days from delirium tremens. Pulse 120 and feeble.

Was given by the house physician Tr. digitalis ʒ i., and, hypodermically, 15 grs. chloral hydrate, within fifteen minutes after admission.

At 11.30 a.m., gave by mouth 60 grs. bromide of potassium, and continued the doses at intervals of three hours during the remainder of the day. Also took Tr. digitalis ʒ i. every three hours.

At night seven and a half grs. chloral hydrate hypodermically. Next morning took Tr. digitalis ʒ ss.

Case III.—Mary M., admitted to hospital with delirium tremens. Pulse weak and rapid. Gave fifteen grs. chloral hypodermically, and ninety grs. potass. brom., by mouth, during first fifteen minutes; also Tr. digitalis ʒ ss. In forty minutes gave one hundred and twenty grs. bromide potassium by mouth, soon followed by seven and a half grs. chloral hypodermically.

Two more doses of bromide, each containing thirty grs. were given during the night, and in the morning fifteen ♏. Tr. digitalis.

These patients remained in the hospital several weeks for other reasons, and there was no evidence of any abscesses at the points of the hypodermic injections, although the chloral solution used was stronger than that employed in Case I., namely, two drachms to the ounce of water.

Progress of Medical Science.

Changes in the Maxillary Bones in Ataxics.—M. Vallin has observed, in several cases of locomotor ataxia, a falling out of the teeth which is not preceded by pain or caries. This phenomenon is due to a bony rarefaction of the alveolar border, as a result of which the teeth simply drop out of the alveoli. It is a trophic alteration of the maxillæ which has not hitherto been described, but which deserves careful study, as it may be an early symptom of the general disease. MM. Luys and Lereboullet have also observed this falling out of the teeth in ataxia.—*Le Courrier Médical,* March 6th.

On the Anatomical Characters of the Blood in Extreme Anæmia.—M. Hayem classes, under the title *aglobulie intense,* all those cases of anæmia characterized essentially by a globular richness of 2,000-000 to 800,000, and under the title *aglobulie extrême,* the cases in which the number of globules varies between 800,000 and 450,000. The following are some of the special modifications of the corpuscular elements which he has observed in these two classes of anæmia:

1. When a thin layer of normal blood is dried rapidly on a glass slide and covered with a cover-glass, the red globules and hæmatoblasts remain indefinitely without losing their hæmoglobine. On the other hand, in similar preparations of the blood of persons affected with aglobulie intense, the hæmatoblasts and a certain number of the red globules are often seen at the end of one or more days to be sur-

rounded with circles of small crystals, which are at first isolated, but subsequently unite to form more or less extended arborizations. This formation of crystals is observed no matter what may be the cause of the anæmia (saturnine poisoning, cancerous cachexia, hemorrhages, etc.). It is observed in preparations of the blood of animals made anæmic by repeated venesections. The crystals are very small, yellowish, or of almost the same color as the dried globules, and variable in form. They present the same appearances in the blood of men and animals. M. Fouqué has found that they have no action on polarized light. While seeking for an explanation of their production, M. Hayem found that the hæmatoblasts of the lymph are almost all transformed in the course of desiccation into minute crystals similar to those found in the blood of animals; absolutely similar crystalline arborizations are found in dry preparations of the lymph of dogs, or of the juice from the lymphatic glands of different animals (dog, cat, rabbit, guinea-pig).

2. When a fresh preparation of the blood in these cases of anæmia is examined, it will be noticed that a number of the white globules contain an abnormal quantity of hæmoglobine, while they, at the same time, retain their physical properties, and especially their amœboid contractility. Desiccated preparations contain then very peculiar corpuscles. These are regularly rounded or oval elements, of large size, and of a yellowish color, which is sometimes almost as pronounced, especially near the edges, as that of the red corpuscles. They are flattened by the process of desiccation, but nevertheless retain a certain thickness, and, as a necessary effect, are surrounded by a dark circle. At first sight these elements might be mistaken for voluminous red corpuscles, but they differ from them in several important points, viz., in the absence of bi-concavity, in the finely granular state of their protoplasm, and in the presence of one or more nuclei absolutely similar to those of the other white globules. They are undoubtedly white globules, which, by virtue of the hæmoglobine they contain, have retained a certain degree of thickness in drying. At times, some of these elements are so deeply colored, that the nuclear mass can scarcely be seen, particularly in recent preparations. These white globules, with colored contents, are much more frequently met with than the crystalline productions. Since 1875, when he first noticed them, M. Hayem has found them in all cases of intense and extreme aglobulie from any cause. They are exact counterparts of the globules found in the lymph of animals.

3. In some cases of extreme aglobulie, white globules, still more strongly charged with hæmoglobine are found. When treated with a fluid which fixes the blood-globules, such as that employed in their enumeration, they appear under the form of irregularly spherical corpuscles, with a yellowish, crenated, and changeable border. In the dry state they are almost always perfectly round, sometimes slightly oval, and are composed of a colored ring surrounding a granular and rounded nucleus. The outer ring is as deeply colored as the red corpuscles, and the whole presents the appearance of a nucleated red corpuscle. This variety of element is rare. M. Hayem has only met with it twice since 1875, both times in cases of extreme anæmia due to cancer of the stomach. He suggests the probability that the nucleated red corpuscles said to be found by some authors in leucocythæmia and pernicious progressive anæmia, and regarded by them as intermediate forms between the red and white corpuscles, were really elements of the above kind. Analogous elements are found in the normal state in the lymph and the red marrow of the bones.

4. Finally, in these cases of extreme anæmia, the small white globules are almost always more numerous than those of normal size, and some of them are as small as the smallest white globules of the lymph.

M. Hayem concludes from these observations, that the blood in these cases of extreme aglobulie contains elements that exist normally only in the lymph and in lymphatic organs, or in other words that it consists of a mixture of blood, properly so called, and of lymph. Instead of considering the above described nucleated colored corpuscles as a transition form between red and white corpuscles, he sees in them a proof of the arrest of the hæmatopoëtic function, and an essential characteristic of anæmia pushed to its farthest limits. When, under these circumstances improvement sets in, and the blood becomes richer, the colored white corpuscles disappear, and at the same time a considerable number of hæmatoblasts and elements intermediate between them and the red corpuscles are produced. From observation of fifty cases of reparation of the blood after different maladies, he states it as his positive belief that the hæmatoblasts are always the precursors of new red corpuscles.—*Gazette méd. de Paris*, March 6, 1880.

New Method of Treating Depressed Fractures of the Nasal Bones.—Dr. Lewis D. Mason states that experiments on the cadaver have led him to conclude, that in all fractures of the nasal bone with depression of the bridge, the nasal processes of the superior maxillæ are necessarily involved, and that the line of fracture is nearly on the same plane on either side. As the usual plans of treatment prove very unsatisfactory, he suggests a new method, which consists in the introduction of a medium sized, three-cornered surgical needle through the lines of fracture of the nasal processes after proper elevation of the depressed fragments. The needle is left in situ, and affords posterior support to the nasal bones, at the same time acting as a tie-rod to hold together the sides of the nasal arch. The needle should be nickel-plated or gilded, and ground to a drill point. A strong needle-holder will be required to pass it. If the lines of fracture be not symmetrical, the nasal process can be drilled through with the needle on either side. The needle will always have three points of support, viz., the nasal processes and the septum. To complete the dressing, a strip of pure rubber bandage is placed over the bridge of the nose by puncturing either end on the head and point of the needle. The rubber should have sufficient tension to exert a gentle downward and lateral compression, but not enough to interfere with the circulation or to exert injurious pressure on the fragments. At the end of the sixth day, or as soon as consolidation is sufficiently advanced to sustain the fragments, the needle may be withdrawn. Anæsthesia will be necessary while passing the needle, and probably when removing it also.—*Annals of the Anatomical and Surgical Society of Brooklyn*, March, 1880.

Thalictrum Macrocarpum.—M. Bochefontaine recently made a report to the *Société de Biologie*, on the physiological properties of the extract of the roots of this plant, which belongs to the order of ranunculaceæ. A series of experiments on frogs and dogs showed that it produces local symptoms of irritation, severe vomiting, diminution of excito-motility and muscular contractility, phenomena of paralytic engorgement of the central nervous system, and retardation and even arrest of the heart's action. Whenever the dose of the extract was sufficient to cause paralysis, it was followed by death. Two principles have been isolated from the extract of the roots: macrocarpine and thalictrine. The former is not toxic; it possesses some of the reactions of berberine. Thalictrine, on the contrary, is very active, and possesses the chemical properties of the alkaloids. It has been found to possess both the toxic properties and the physiological action of the extract of the roots of thalictrum. In its physiological properties, thalictrine seems to resemble aconitine.—*Le Progrès médical*, March 20, 1880.

LOCAL ANÆSTHESIA BY BROMIDE OF ETHYL.—M. Périer, of Paris, states that he has employed the bromide of ethyl several times as a local anæsthetic with considerable success. It has the advantage over ether of not being inflammable, and hence can be employed when the actual cautery is to be used.—*La France médicale*, March 27th.

AN UNDESCRIBED VARIETY OF FRACTURE OF THE FIBULA.—M. Duplay has recently met with two cases of an undescribed form of fracture of the upper extremity of the fibula. Both the patients had been caught in the belting of machinery. Just above the site of the upper extremity of the fibula, there was in each case an immovable bony prominence to which the tendon of the biceps was attached. Below this prominence there was a distinct depression. Evidently a portion of the head of the fibula had been torn off. The diagnosis was easy in both cases. One of the patients had multiple fractures, and, moreover, complete paralysis of the extensors of the foot and the peronei muscles, due to a lesion of the external popliteal nerve. The other patient died suddenly, before there was time to ascertain whether or not paralysis of the muscles existed. At the autopsy it was found that the nerve passed around the fractured end of the bone, and hence it was probably involved in the lesion. In the former case it is probable that osseous consolidation will not take place, but the patient will probably get fair use of the leg, although the paralysis seems to be permanent. When the patient left the hospital, some months after the accident, the paralysis still persisted, and later advices show that the condition remains unchanged in this respect.

M. Perrin reports a similar case, caused by a horse falling on the rider's leg. The head of the fibula was torn off, and there was some effusion into the knee joint. In this case also there was anæsthesia and complete paralysis of the anterior and outer aspects of the leg.—*La France médicale*, March 27th.

ON THE TREATMENT OF MALARIAL FEVERS BY THE ETHEREAL OIL OF MUSTARD.—Dr. Tabercorn reported to the Caucasus Medical Society, that he had obtained very brilliant results with the ethereal oil of mustard, in many cases of malignant malarial fevers while he was stationed in Moldavia. He prescribed from 2–3 drops of the oil in a large quantity of boiled water, or, what is better, from 2–4 drops in a 10 % alcoholic solution. In garlic, onions, horseradish, etc., are present substances allied to the mustard oil, and these vegetables are eaten extensively by the inhabitants of the marshy districts for their prophylactic properties. The oil is also an excellent antiseptic, destroying bacteria in the solution of 1 part to 900. —*Meditz. Obozrenie, February*, 1880.

IODINE IN INTERMITTENT FEVERS. — Dr. Stepanoff finds iodine efficient mainly in recent cases of intermittent, and particularly if the temperature does not rise above 39° C. But it does not prevent the recurrence. — *Vratcheb. Vedom. NNo.* 395–399.

MILK IN THE LOCAL TREATMENT OF DIPHTHERIA. — Dr. Karnitzky speaks very highly of milk as a gargle or atomizing fluid in the treatment of not very severe cases of diphtheritic sore-throat. The milk should be as fresh as possible, about 22° C. and can be diluted half or one-third with lime water.—*Vratscheb. Vedom. No.* 403.

EFFECTS OF FARADIZATION OF THE LIVER ON THE EXCRETION OF UREA.—As the result of very carefully conducted experiments, Dr. Sigrist comes to the conclusion that faradization of the liver makes its circulation more active, and consequently leads to an increase of the excreted urea. In one case the amount of urea was raised from 18–20 grms. to 35 grms., and the size of the liver became perceptibly larger.—*Vratsch.*, 1880, *No.* 2.

FOUR CASES OF AMPUTATION OF THE INVERTED UTERUS.—The cases which are the subject of Dr. Vadiagin's report, were from 21–35 years old, disease lasting from 1 to 3½ years, all of puerperal origin. Operation was called for by excessive hemorrhages resisting most energetic treatment, and by inability to reduce the inversion. The removal of the uterus was accomplished in each case by a wire ligature placed close to the cervix, and tightened every day until the organ dropped off. This occurred on the 8th, 9th, 11th, and 15th days. In the first three cases fever was mild and septic, complications slight. But in the last one, the ligature, on account of the severe pain, could not be made sufficiently tight, which occasioned slower separation and more marked constitutional disturbances. All recovered.—*Meditz. Obozrenie, April*, 1880.

HEARING BY THE AID OF TISSUE-CONDUCTION.—THE MOUTH-TRUMPET AND THE AUDIPHONE.—Dr. Samuel Sexton has published a paper explaining the *modus operandi* of hearing through the tissues of the head with the mouth-trumpet and the audiphone. One of these conditions he believes to be more or less change in the membrana tympani, especially its loss of proper tension from trophic changes, or from results of inflammatory action; thus impaired, the membrane fails to perform its vibratory function in a normal manner. Or, the excursions of the membrane may fail of transmission to the labyrinth through displacement of the articular surfaces of the ossicula, the normal tension of the conductive apparatus of the middle ear thus being no longer maintained. When the integrity of the membrana tympani and the chain of ossicles is thus impaired, sound-waves received by the teeth, or other parts of the head, may be transmitted through the bones, muscles, and other tissues of which the parts are composed, to the auditory nerve. Practically, Dr. Sexton has found that tissue-conduction permits of conversation with the deaf by means of a mouth-trumpet—a short tube of rubber extending from the speaker into the patient's mouth—although in an experience of some years he has not been able to satisfy himself that it is of value for general use. He recommends it, however, as promising good results, if used in the instruction of some deaf mutes who hear their own voice, but require the aid of normal sounds in order to learn to speak. Voice is heard by means of the audiphone in the same way as through the mouth-trumpet, but the transmission in this case being affected through an uninterrupted and direct osseous route from the teeth to the ears, it is heard much more loudly; by no means, however, in a natural tone.

Dr. Sexton found that one patient, cited as an example, could hear the distinct voice of one person a few feet only, and that, although he had practised with the audiphone of Mr. Rhodes for several months, he could hear no better with it than when he used it first. One patient, a lady, found the use of the instrument made her quite nervous, attempts to hear conversation at all well being quite ineffectual. It was observed that this lady had suffered loosening of a tooth from the pressure (and vibrations?) of the audiphone when in use. The author's patients found the audiphone inconvenient to carry about and exceedingly liable to be broken. Dr. Sexton concludes, from observations made on a number of patients who have used the audiphone, that, as at present constructed, its range of usefulness is rather limited, but that those who experience autophony—hearing their own voice—can derive more or less benefit from it if properly constructed. The writer does not doubt that, when a knowledge of tissue-conduction of the head is more general, better instruments will be devised.—*The American Journal of Otology*, April, 1880.

ON NERVE-STRETCHING.—Dr. A. Gen collected 73 cases of nerve-stretching used as a therapeutic measure. In traumatic neuralgia it was employed 6 times—cured 4, improved 1 (recovered entirely after neurotomy), no improvement 1. In neuralgia from other causes, in 14 cases—cured 10, improved 3, 1 died from the hemorrhage. In clonic spasms and contractions, 6 times—cured 4, no improvement 2 (one cured by neurotomy). In peripheral epilepsy, once—cure. In tetanus, 16 times—cured 7, symptoms improved but disease terminated fatally in 6, symptoms did not improve and patients died, 3. In anæsthetic leprosy, 30 times, in all cases with marked benefit.

As the therapeutic action of nerve-stretching is not well understood, he performed some experiments in the laboratory of Prof. Tarchanoff with a view to determine it. Some of his conclusions are as follows: Not only mild stretching, but also the use of force equal to half what is necessary to rupture the nerve, may produce an increase of its irritability and conduction. Mild stretching has no effect upon the reflex irritability, but if the force used be great, it is diminished; this effect is also observed on the opposite side, indicating the central seat of the change in its effects. Hence the operation is not limited to the peripheral parts only of the nerve, as Vogt was inclined to think. Under the microscope he found the traces of hyperæmia and capillary hemorrhages; the axis-cylinders and myeline may be severed, but the Schwan's sheath is intact. He found also peculiar constrictions in the medullary fibres. He considers that the diminution of the reflex activity is the main feature, and in the cases operated on was the condition called for.—*Voyenno-meditsinsky Journal*, December, 1879.

ABSCESS OF THE LIVER—PUNCTURE—RECOVERY.—Dr. Jschulovsky reports the following: On admission of the patient, a tumor of the size of the child's head was found in the right hypochondriac region, elastic to touch, uniformly soft, not painful, and with indistinct fluctuation. Temperature normal. By means of the aspirator five lbs. of a yellowish green, bad-smelling pus were withdrawn. On the fourth day the abscess became as large as ever, and it was evacuated through a trocar; with the pus, thirty biliary calculi not exceeding the size of a pea escaped. During the following two weeks, from ten to thirty similar stones came away through the opening nearly every day. Fistula was healed in a month from the beginning of the disease.—*Vratschel Vedomosti, Nos.* 380 *and* 381.

SALICYLATE OF SODA IN TYPHUS FEVER.—Dr. Ter-Grigoriantz used this drug in sixteen cases of typhus fever with very beneficial effect. In no case was there violent delirium, and only one patient suffered from a mild delirium; the action of the heart became stronger; there was no recurrence of the disease; all the patients recovered and left the hospital after an average stay of twenty-five days, looking remarkably vigorous. No injurious effect was observed on the kidneys, but in one case the face became œdematous. Two ounces of salicylic acid were administered in the course of twenty-four hours.—*Meditz. Obozrenie*, February.

TREATMENT OF CHOLERA INFANTUM.—Dr. Böing, of Uerdingen on the Rhine, states that he had remarkable success in an epidemic of cholera infantum last year with a treatment consisting of large doses of quinine and wine. He treated about fifty cases between two months and four years of age, and all recovered. Some of the children under one year of age were being brought up by hand. The quinine was given in divided doses every half-hour or hour, in a menstruum consisting of equal parts of mucilage, syrup of chamomile, and distilled water. To children under 5 months of age, 15 grains of quinine were given in 24 hours; to children from 5 to 10 months old, from 18 to 22 grains, and to children from 10 months to 4 years old, from 22 to 30 grains. When the dejections and vomited matters were acid, the addition of testa prep. or phosphate of lime seemed advantageous as long as the urine had an acid reaction, but seemed to increase the vomiting when the urine was alkaline. The wine used was Tokay; for the youngest children it was diluted with equal parts of boiled water, and a teaspoonful to a tablespoonful given every quarter-hour or hour. A moribund girl, three years of age, took nearly a pint of wine in 24 hours. Milk was given boiled and diluted with equal parts of boiled water. In some of the cases everything was vomited at first, but the treatment was persisted in, and after a short time the stomach retained all that was given. For the poorer patients a mixture containing acetic ether (♏. lxxv. pro die) or spirits of acetic ether (℥ ss. pro die) was substituted for the wine. The acetic ether was used in preference to sulphuric ether, on account of its more agreeable taste and smell. Some of the patients were unable to swallow when first seen. In these cases several subcutaneous injections of acetic ether were first administered at short intervals, and the Tokay was then given in teaspoonful or tablespoonful doses, the spoon being passed deeply into the mouth and the tongue pressed down before the spoon was emptied. After a brief persistence in these measures, the children invariably regained the power of swallowing. Dr. Böing states that he confined himself strictly to the above treatment in all of the cases, and that he regards calomel, opium, and cold applications as dangerous remedies. Should the treatment fail in any future trials, he proposes to give the quinine subcutaneously, or in doubled doses by injection. To relieve the thirst he would then give boiled water containing a little salicylic acid.—*Allg. med. Cent. Zeit.*, June 26th.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, August 14, 1880.

THE AMERICAN ASSOCIATION OF MEDICAL COLLEGES.

An examination of the official report of the fourth annual meeting of the American Medical College Association reveals an apparently anomalous state in the affairs of this organization. There are in the report confident assertions of the prosperity of the Association, but there are, on the other hand, certain facts stated which do not appear so promising. It will be seen from our abstract of the report in another column that the membership has increased in the past year from twenty-nine to thirty-one. So that the Association now embraces one-half of the colleges of the United States. It claims to have secured progress as regards medical education in seven different directions, and the claims are to some extent just. The reports of the special committees are independent in tone, and show a thorough appreciation of the evils that need remedying. And, finally, the Association has had the courage to take the step of insisting upon three full courses of lectures as a requisite for graduation.

But in spite of all this evidence of earnest endeavor after reform, we find that none of the largest medical colleges are working with the Association. Not one of the colleges of Philadelphia, New York, or Boston, were represented at the meeting, except the Jefferson Medical College, and its delegate failed to vote for the resolution requiring a three-term course. The College of Physicians and Surgeons of this city, and the Bellevue Hospital Medical College, and the Vermont University Medical College, withdrew from the Association altogether. It is composed, therefore, now, for the most part, of the smaller medical colleges scattered throughout the west and south.

This disaffection of the Eastern colleges has, we fear, an unfortunate significance. If we interpret it rightly, it means that the Association can do them no good and that they do not have faith in the possibility of securing any great reforms in medical education through its influence. There certainly is some reason for looking at the matter in this light. The Association is composed largely of colleges which really can not subscribe to certain most desirable measures without ceasing to exist. One of these reforms—the one perhaps of least importance—is that of raising the lecture-fees. An attempt to make a rule on this point at the last meeting failed utterly. There is a very sharp competition among some colleges, and one form which this takes is the practice of underbidding each other in the matter of fees. This practice, which is very demoralizing, the Association cannot stop. Another reform which is greatly needed is the insisting that a medical college should furnish a certain amount of clinical instruction. But there are a good many country colleges, where a rule enforcing even a small minimum could not be carried out.

The fact is, therefore, that a high minimum of requirements for graduation—a minimum embracing all points desirable to secure a thorough medical training—can never be applied to all American colleges, and can never be adopted by the College Association without a fatal loss of membership. A minimum that would, perhaps, elevate and benefit small colleges would be inadequate for the institutions of the great cities.

It is with great regret that we express this doubt in the future possibilities of the American Medical College Association. It has certainly done some good work, but, under its present methods, it has, we fear, done nearly all that it can. We see no way out of the difficulty, except by openly acknowledging the facts that exist, and by devising, if possible, some new plan for surmounting them. It seems very much as though the only possible solution will be in adopting two standards of minimum requisites for graduation. This would not be at all inappropriate to our medical institutions. We have two classes of colleges, the one in which didactic and clinical instruction are united in equal degrees of prominence, and the other in which the teaching is almost entirely didactic. The latter class embraces institutions which, though small, are often very useful. The most they can do, however, in the way of reform, will be to lengthen their courses, elevate the standard of their examinations, and increase the amount of didactic instruction. A general minimum of requisites for graduation, which would apply to this class, would not be sufficient for the large colleges; hence the propriety of a double standard. The country colleges should accept the fact that their function in medical education is a limited one, and they should be content with the position of a lower grade college. It is not a thing about which there could be any hesitation among thoroughly honest and disinterested men. It is almost a crime to graduate a medical student without giving him practical clinical teaching. We commend the matter to the attention of the Medical College Association, with the earnest hope that some measure in the direction indicated may be devised and eventually carried out.

SUICIDE AND HOT WEATHER.

The vital statistics of Philadelphia show that during the past hot weather twenty-four persons have committed suicide. This fact has suggested the query whether hot weather has any causative relation to the increase in the cases of *felo de se.* The statistics of European countries, recently collected and studied by a writer in *Blackwood's Magazine*, show that it has such relation very decidedly. Some interesting facts are presented in discussing the subject. It is not in cold or wet, but in fine weather that Europeans kill themselves the most. The returns indicate with glaring distinctness, says the writer referred to, that spring and summer are everywhere the great suicidal periods; that November is about the most innocent month in the year; and that May, June, and July are the worst—so much the worst, indeed, that twice as many suicides habitually happen in each of them as in any winter month. The average rises, almost regularly, from November to May, and goes down again, in equivalent degrees, from July to November. It is a curious fact also, that, although the natives of hot countries slaughter themselves less than those of cool climates, nevertheless heat does seem to be an incentive to self-murder in these latter regions. In Algeria, for instance, where a good many French soldiers kill themselves from homesickness, it has been remarked that the moment ordinarily chosen is when the south wind blows and brings up from the desert its scorching, irritating dryness. This, with other facts, tends to prove that dampness has not that fertilizing influence on suicide with which it has been credited, and the old theory that suicides in England are mainly caused by the fogs is disproved.

Regarding this influence of climate, it has only recently been shown that it has no effect in producing suicide. Thus, in the comparative catalogue of national suicide, England stands below the middle of the list; but Norway is high up in the table; Denmark is at the very top, while Russia is low down in it. Yet the climates of these countries present such analogies that, so far as regards their action on the character of the people, they may be considered identical. The Esquimaux do not kill themselves at all, neither do the Falkland Islanders; yet the climate in which they live is certainly worse than that of Scandinavia or England.

In estimating the increase of mortality that is caused by hot weather in temperate climates, therefore, we must include that induced by an increase of suicidal tendency. Deaths from this cause are, of course, beyond the reach of the sanitarian. The mortality is not, in any given locality, a large one, yet it is by no means insignificant. In Europe 60,000 persons kill themselves annually; and, assuming that about the same rate exists with us, there are nearly 10,000 Americans who kill themselves every year.

PHARMACOPŒIAL WEIGHTS AND MEASURES.

There is danger that the forthcoming pharmacopœia of the United States will be disregarded by many of the physicians and pharmacists on account of the abolition of fluid measures. It is of course optional with physicians whether or not they will prescribe exclusively by weight. For the adoption of "parts by weight only" in the pharmacopœia is one thing, and the discontinuence of volumetric methods in writing and dispensing prescriptions is another, which does not necessarily follow from the first. That liquid remedies must be given to patients by measure is, however, undeniable, and physicians will be apt to write their prescriptions in the manner best adopted to the end in view. Fluid measures are the only direct and convenient means; they are nearly as accurate as weights, and will therefore continue to be used. The pharmacists of this country, having been so long accustomed to measure liquids, will probably find the new method troublesome.

Professor Oldberg's paper on the subject in this number of the Record strongly indicates that the metric system, including fluid measures, would have been far preferable.

ANÆSTHESIA IN DENTISTRY.

The New Jersey State Dental Association, at its recent meeting, passed a resolution to the effect that its members should avoid the use of anæsthetics as much as possible, and that in every case requiring anæsthesia the greatest care should be taken to insure the safety of the patient by a preliminary examination into his physical condition. Under ordinary circumstances the precautions advised would be considered altogether unnecessary; but, coming from a body of dentists, and with the formal sanction of a deliberate society vote, they have more than an ordinary significance.

It need not be stated that dentists, as a class, are addicted to the free use of anæsthesia; neither is it necessary to assert that a large proportion of fatal cases, especially with chloroform, have been associated with dental operations. Hence, it appears peculiarly appropriate for a society of dentists to give the matter such serious attention as is indicated by the resolution to which we have referred.

The injunction to abstain from the use of anæsthetics whenever such a thing is possible will not have, practically, much force with dentists. The desire of a patient to avoid pain, and the inclination of the operator to oblige him, are two powerful elements which will always argue in favor of anæsthesia. Besides, the public are educated to the belief that for tooth-extraction pain is not necessary. The administration of some sort of anæsthetic is now considered to be a necessary condition of the operation, and the dentists who fail to meet the want are in danger of losing custom. It can hardly be expected that any dental operator, under such circumstances, will strain a point to persuade a patient not to be rendered insensible to pain; but, if the other part of the resolution is conscientiously carried out, viz., the preliminary examination into the physical condition of the patient, many fatal accidents may be prevented.

Reviews and Notices of Books.

Health and Health Resorts. By John Wilson, M.D., late Medical Inspector, U.S.A. Philadelphia: Porter & Coates. 1880.

The title of this book is a somewhat pretentious one, for there is not very much about health, and only foreign health-resorts are described. To that comparatively small class of persons which goes abroad for its health the book will furnish considerable useful information. The remarks upon the regimen for invalids at health stations are judicious and show familiarity with these places. The author discourses learnedly upon the influence of electricity in producing climatic changes, but the bearing of his theories on health and health-resorts is not very apparent. The chapters upon mineral springs and winter health resorts have about the merit of an ordinary guide-book. The book will have some practical usefulness, but, on the whole, it is a rather weak effort.

The Thirteenth Report of the St. John's Hospital, at Lowell, 1879, contains an interesting account, by Dr. Nathan Allen, of the Hospital Sunday movement, and its success in this country.

Retention of the Placenta after Abortion. By B. B. Brown, M.D.

Several cases illustrating this rare accident are here related. A bibliography of the literature of the subject is appended, which makes the pamphlet a valuable one.

On New Methods of Operation for Repair of the Female Perinæum. By Lawson Tait, F.R.C.S., etc.

Mr. Tait's new operation is based on two principles: first, that no tissue is removed, flaps being lifted only; second, that the stitches instead of being interrupted and applied through the thickness of the flap, are applied in the axis of the wound and are practically continuous. The reprint describing this operation is well illustrated, as would be necessary indeed to make the process clear.

I. Surgery in the Pennsylvania Hospital. Being an Epitome of the Practice of the Hospital since 1756; Including Collations from the Surgical Notes, and an Account of the more Interesting Cases from 1873 to 1878. With some Statistical Tables. By Thomas G. Morton, M.D., and William Hunt, M.D., Etc., Etc. Philadelphia: J. B. Lippincott & Co. 1880. 8vo, pp. 319.

II. Montreal General Hospital. Reports, Clinical and Pathological. By the Medical Staff. Edited by William Osler, M.D., M.R.C.P., London. Vol. I. Montreal: Dawson Brothers. 1880. 8vo, pp. 369.

I. The first of these works is based mainly upon the cases recorded in the hospital since 1873, the records extending as far as 1752, being made use of when deemed necessary. Many of these cases have appeared in the various medical journals from time to time. The first article on "Amputation" contains the statistics of 108 operations performed on 100 patients and extending over the period between 1875 and 1879. From these it would appear that in 59 cases in which the amputation was primary, 45 were cured, 13 died, and 1 was removed from the hospital. Of the 11 secondary amputations, 10 were cured and 1 died. There were 38 amputations for bone and other diseases; of these 34 were cured, 3 died and 1 was removed. Of the 34 amputations at the upper extremity, 4 died; of 74 at the lower extremity, 13 died. From the table giving the number of amputations performed from 1830 to 1879, we find that there were 1,011, of which 247 died. Statistics are also given of various other surgical diseases, the more prominent being "aneurisms," "erysipelas," "cancer," "elephantiasis," "ovariotomy," and "fractures." An interesting account of the construction of the hospital, the mode of ventilation, and hospitalism is furnished by Dr. Morton. Then follows a list of the medical officers of the institution, prepared by Dr. Longstreth. The volume concludes with an abstract of the surgical cases treated from May, 1873, to May, 1878, prepared by Mr. Jonathan Richards, the whole number being 5,580, of whom 390 died, 3,134 were cured, 996 improved, and the remainder, with the exception of 490, who were in the hospital when the report was made, were lost sight of. The book contains an engraving of the hospital, one phototype, and several illustrations. It will be of great service as a book of reference to those interested in surgery.

II. We hail with pleasure the appearance of the first volume of these reports. The editor, in the preface, gives a brief account of the hospital accommodations, there being 170 beds and an average of about 1,600 in-patients admitted during the year, and 15,000 out-patients treated. In the year commencing May, 1878, and ending April 1, 1879, there were 1,552 patients treated in the medical and surgical wards of the hospital, of whom 1,416 recovered, and 136 died. The first paper "On hemocythæmia," by Dr. R. P. Howard, contains the histories of several cases, the pathological conditions found, together with views of different authors in reference to the disease. A "Remarkable Case of Favus," is described by Dr. T. G Roddick, in which almost the entire scalp was affected, together with a greater part of the body, the hands and feet being free from the disease, The same writer gives the statistics of Lister's antiseptic method, as practised in the hospital. From this we find that in 64 operations performed, there were but two deaths, one being a woman, fifty-five years of age, in whom the leg was amputated, and who died from exhaustion during the third week, a post-mortem examination revealing an aneurism of the common iliac, with closure of the vessels from that point. The other case was one of morbus coxæ in an advanced stage. The "Pathological Report" of Dr. Osler is quite full and exhaustive, comprising a selection from 225 post-mortems. There are other papers by Dr. Osler and the members of the hospital staff, which are of value and interest. There are several excellent plates interspersed through the book, which are well gotten up. We congratulate the editor on the great amount of material that has been brought together, and hope to see the "Reports" continued from year to year.

Catalogue of the Graduates and Officers of the Medical Department of the University of the City of New York. December, 1879. Second edition. Published by the Alumni Association. 8vo, pp. 159.

The catalogue contains a history of the Medical Department of the University. A list of officers is then given, after which are the names of the alumni, together with their residences and the different offices they have held. The class of 1879 is to be found in this edition.

A Reply to Criticisms on the "Problems of Insanity," with Remarks on the Gosling Case. By Dr. Geo. M. Beard.

This pamphlet embraces Dr. Beard's closing remarks during the discussion of his paper on the Problems of Insanity, before the Medico-Legal Society. It makes quite interesting reading and is one of Dr. Beard's best literary efforts. It has a good deal of glitter to it, and it contains several striking and suggestive points; but we doubt if it makes very much impression on the scientific mind. Dr. Beard's definition of insanity is as elastic and meaningless as other efforts in the same direction.

What Constitutes a Discovery in Science. By Dr. Geo. M. Beard, A.M., M.D.

In this little brochure of five pages, Dr. Beard endeavors to show that he is the true discoverer of neurasthenia. The argument is made up of lurid rhetoric, shallow analysis, and pretentious logic. Dr. B. is undoubtedly entitled to much credit in the matter of delivering this new pathological infant, neurasthenia, but critics on the whole have done him ample justice, and the present performance seems to be quite uncalled for.

One Thousand Deaths in "The Knights of Honor." By Joel Seaverus, M.D.

This is the title of a short article in which the different proportion of mortality in the different States is shown. It appears, for example, that in Kentucky the proportion of deaths was 1 to every 42 members, while in Massachusetts it was 1 to 89. The facts brought out will be of value to co-operative life insurance companies and mutual benefit societies like The Knights of Honor.

Report of the Proceedings in the Case of Ruths vs. Reuling.

The trial for malpractice, of which the present pamphlet is a record, excited much interest and feeling in Baltimore at the time of its occurrence last March. Dr. Reuling, a reputable physician and oculist, operated on a woman for acute glaucoma; the operation failed, partly through the fault of the patient, and she was left blind—the condition to which the disease itself would have in any event brought her. The woman and her friends appeared to be satisfied, and continued friendly toward Dr. Reuling until about three years later. At that time, partly through the hints and instigation of a "brother" oculist, a trial for malpractice was instituted. This came off last spring. An attempt was made to show that the diagnosis was wrong, and the operation uncalled for. The attempt was a signal failure, and Dr. Reuling was completely acquitted. The affair was an unfortunate one, and did great injustice to the defendant.

A Paper on Color-Blindness. By Dr. B. Joy Jeffries.

Read before the U. S. Naval Institute, gives a brief and clear statement of the principal facts regarding color-blindness.

Notes on Perityphlitis, by Henry B. Sands, M.D.,

is the title of a paper giving the results of the study of twenty-six cases of perityphlitis that occurred in the author's experience. The observations here made will be of use to persons who wish to refer to the subject, though they embrace nothing especially new. The treatment by early incision, introduced by Dr. Willard Parker, is endorsed.

Protection from Venereal Diseases in America. By Dr. J. Birbeck Nevins, London.

This is the reprint of an article that appeared in *The Sanitarian*, a short time ago, in answer to the address of Dr. H. L. Gihon, delivered before the Public Health Association, and subsequently published in the same journal. Dr. Gihon portrayed, in somewhat lurid colors, the evils of syphilis to the human race, and urged the great necessity of taking strong measures to stamp it out. Dr. Nevins deprecates the rhetoric and calls in question some of the statements of Dr. Gihon. The former gentleman would have us believe that syphilis is not such a terrible scourge as has been represented. He shows that in England the total deaths from syphilis are only 1 out of every 374. Out of 60 diseases tabulated in the order of their fatality, syphilis ranges from forty-second to forty-fifth. Out of an annual average of 1,201 deaths from syphilis, 1,037 occur within the first year of life. Dr. Nevins does not think that hereditary syphilis is so severe or frequent as has been supposed. Among 266,846 patients in ten children's hospitals in Great Britain and Ireland, only 1.4 per cent. were entered as syphilitic.

Dr. Gihon, in a subsequent number of *The Sanitarian*, published a short reply to the present article. Each author writes as a controversialist, but Dr. Nevins has undoubtedly collected the most facts and has made the better showing for his side.

Contributions to Orthopedic Surgery, including Observations on the Treatment of Chronic Inflammation of the Hip-, Knee-, and Ankle-joints by a New and Simple Method of Extension—the Physiological Method; and Lectures on Club-foot, Delivered at the College of Physicians and Surgeons (Special Course). By Jos. C. Hutchison, M.D. New York: G. P. Putnam's Sons. 1880.

Orthopedic surgery has received a very wide attention and innumerable contributions during the past forty years. But in all the literature of this subject nothing has been shown so clearly as that the theories regarding the best method of treating diseases of the joints are absolutely valueless. At the present time it is announced by the highest authorities, on the one hand, that, in treating diseases of the joints, rest and immobility are the great indications to pursue, and, on the other, that extension with mobility are the *sine qua non*. There is no surgeon who has not his pet theory in which a different degree of prominence is given to rest, extension, compression, immobility, mobility, or expectancy. There is, we must conclude, but one test for any special method of treatment, and that is the test of practical results. On Dr. Hutchison's special method, therefore, of treating diseases of the hip, knee, and ankle, we pass no judgment. The method is simple, inexpensive, can readily be changed if ineffective, and on these grounds deserves a wide trial by the profession. It consists simply in elevating the sound limb by placing a raised shoe on the corresponding foot and letting the child go on crutches. The weight of the limb makes sufficient extension, and the fear of pain secures sufficient immobility. The objections which naturally occur are, that the constant extension may be injurious to the knee-joint, and that the time of extension is not sufficiently long, as it is only applied during the two or three hours a day when the child is walking about. To remedy this latter point, Dr. Hutchison, in some cases, uses night extension by weight and pulley. And he claims that the results of his method have been very satisfactory, much more so in fact than those obtained by the employment of the ordinary mechanical appliances. We agree with the author that Sayre's and Taylor's splints secure neither mobility in the joint nor the extension which is claimed ; and it would be a blessing to afflicted children if the plan offered by Dr. Hutchison, which does away with a cumbersome and often entirely useless harness, could be proved a successful one.

Dr. Hutchison's lectures on Club-Foot have already appeared in The Record, and do not need extended comment here. They are clear and practical discussions of the subject ; and are very well illustrated.

The Surgery, Surgical Pathology, and Surgical Anatomy of the Female Pelvic Organs. In a Series of Plates taken from Nature, with Commentaries, Notes, and Cases, by Henry Savage, M.D., London. Third edition, revised and greatly extended. Thirty-two plates and twenty-two wood engravings, with special illustrations of the operations on vesico-vaginal fistula, ovariotomy, and perineal operations. New York : Wm. Wood & Co. 1880. Wood's Library of Standard Medical Authors.

The publishers of this volume deserve great praise for the enterprise which has placed so valuable and heretofore costly a work within the reach of every practitioner. The plates with which the book is filled are anatomically accurate, and, artistically, are perfect specimens of lithographic art. Dr. Savage's long experience, and his connection with Spencer Wells, entitle him to speak with authority upon the various surgical and pathological points which he discusses. The book treats first of the anatomy of the female perineum. This part of the subject is illustrated with seven plates, accompanied by descriptions and surgical hints in regard to pelvic abscess, pudendal hematoceles, etc. The anatomy of the pelvic contents and their relations is then described, and illustrated with ten plates, besides woodcuts. Under this head Dr. Savage gives an excellent summary of the neoplasms of these parts. In the classification of these tumors, the author inclines to the greatest simplicity, and is of the opinion, to which every one will agree, that nomenclature has hitherto proved more a hinderance than a gain to pathology. The remainder of the book is chiefly devoted to plates and cuts illustrating operations on vesico vaginal fistula, ovariotomy, and perineal operations. Under the head of ovariotomy, he gives the steps of the operation as performed by Spencer Wells. Under all the heads are short and practical commentaries, together with histories of cases which are remarkable for the compactness and point with which they are related.

Dr. Savage is inclined to be aphoristic in making his surgical comments, and he sometimes infers practical rules from purely anatomical considerations in a too dogmatic fashion. An instance of this is his conclusion that the uterus can hardly be amputated without a fatal result from hemorrhage. It will, perhaps, pain a certain eminent gynecologist to learn that nothing is said about the ductility of the uterus. A defect in the book that will be more widely felt, is its lack of an index.

It is needless to go into further analysis, as the book is one that must be seen in order that its merits may be fairly appreciated. It is an exhaustive anatomical, and an almost indispensable surgical guide to the parts of which it treats.

Carlsbad and its Natural Healing Agents, from the Physiological and Therapeutical View, by J. Kraus, M.D., with notes introductory, by Rev. J. T. Walters, M.A. Second edition. Revised and enlarged. London : Trübner & Co., Ludgate Hill. 1880.

This little book embodies an attempt to write up the Carlsbad Springs in a strictly scientific manner, and to furnish physicians with a thorough knowledge of the properties of the waters. There is rather more of scientific information than is generally found in water-cure guide-books, but the general tenor seems to be that Carlsbad water cures pretty nearly everything, especially if the patient is "under the providential care of Dr. Kraus," as was the case with the reverend writer of the introductory notes. Not many physicians send patients to Carlsbad, but if they intend to do so, doubtless a perusal of this book would give additional intelligence and confidence to their counsels.

Mr. Tait's Cases of Oöphorectomy.—Mr. Lawson Tait publishes, in the *British Medical Journal*, a synopsis of all the cases, twenty-eight in number, on which he has performed oöphorectomy. In twenty-six cases of complete operation there was but one death. The results were, at date of the report : complete relief in 18 cases ; great relief in 6 cases ; partial relief in 1 case ; no complete record in 1 case ; death in 1 case. This last was a patient suffering from myoma, and nearly moribund with hemorrhage at the time of operation. The causes for the operation were : dysmenorrhœa in 11 cases ; menstrual epilepsy and mania in 2 cases ; menorrhagia in 2 cases ; hemorrhage from myoma in 10 cases ; abscess of ovary in 1 case. Fourteen of the patients were single ; the ages varied between twenty-five and fifty. Mr. Tait lost one of the two cases in which he performed incomplete ovariotomy. He is of the opinion that unless the ovaries can be entirely removed they had better not be touched.

Reports of Societies.

THE NEW YORK SOCIETY OF GERMAN PHYSICIANS.

Stated Meeting, May 28, 1880.

Dr. W. Balser, President, in the Chair.

CONGENITAL ATRESIA OF MEATUS AUDITORIUS EXTERNUS.

Dr. Scharlau exhibited a child showing this abnormal condition on the right side. In addition to the atresia of the external meatus, the child also had an incomplete development of the pinna of the same side.

Dr. Knapp stated in reference to this case, that bilateral atresia was of very rare occurrence, and that such patients frequently showed, in addition to the arrested development, traces of the original cervical fissures. In this particular instance, the two small superficial fistulæ which appeared near the site of the meatus, might be regarded as remnants of the cervical fissures. In most cases of this kind, he added, the internal auditory apparatus was also found in a condition of malformation, so that operative interference offered no chance of a successful issue.

PERFORATING DUODENAL ULCER.

Dr. Caille presented a specimen of the above, removed from the body of a man 55 years of age, and gave the following history: The patient had complained for some years past of dyspepsia, and he had latterly taken large quantities of hydrochloric acid. Some time before his death he had some pains in the umbilical region. Pressure here would aggravate the pains. Symptoms of enteritis then came on, and were rapidly followed by diffuse peritonitis.

At the autopsy, the upper portion of the horizontal part of the duodenum showed a perforating ulcer. In referring to the mode of development of these rare ulcers, it was stated that the self-digestion of a primary hemorrhagic infarction would account for the origin of the lesion. In this case bloody stools had not been observed.

Dr. Langmann remembered a very similar case which had been previously reported at one of the meetings of the Society, by Dr. Schnetter. Intestinal hemorrhage had, however, been a prominent symptom in that case.

CONGENITAL ATROPHY OF LIVER.

Dr. Jacobi presented a specimen of what he considered a true interstitial hepatitis, occurring in an infant weighing ten pounds. The liver weighed only one ounce and a half, and was composed almost exclusively of connective tissue. (See Medical Record, June 5, 1880, p. 648.)

◆

Another Diploma Shop Discovered.—A medical school or college which appears to have been trafficing in diplomas has recently been discovered, it is said, in Kansas City, Missouri. From the circumstances surrounding the matter it would seem probable that the officers of the institution, if it be entitled to the name, are successors in business and perhaps descendants by name of some of the Philadelphia worthies renowned in same sort of transactions.

NEW HAMPSHIRE MEDICAL SOCIETY.

Ninetieth Annual Meeting,

Held in Phœnix Hall, Concord, June 15 and 16, 1880.

First Day—Morning Session.

The meeting was called to order by the President, Dr. T. J. W. Pray, of Dover, and prayer was offered by Rev. D. C. Roberts, of St. Paul's Church, Concord, after which the usual committees for the session were appointed, and delegates (Drs. Ira A. Russell and George W. Gay, from Massachusetts, and Dr. George Davenport, from Vermont, societies) were introduced, welcomed to seats, and invited to take part in the proceedings of the Association.

There were one hundred and twenty members present.

The Council Meeting was held the evening previous, and the report was read by Dr. M. W. Russell, Secretary, and was accepted, after which sixteen new members were elected and took seats with the Society.

DIPHTHERIA.

At 12 m., the President, Dr. Pray, read the annual address, choosing for his subject Diphtheria, discussing the etiology and the pathological conditions usually found, and making a strong appeal to physicians always to examine carefully and persistently into the sanitary conditions of the house and surroundings in cases of this disease, and gave some excellent hints as to the indications of a tonic plan of treatment. He closed with a brief summary of his own observations, saying he was convinced that croup and diphtheria were of the same origin, and essentially the same in development.

The address was accepted with a vote of thanks, and Dr. W. T. Smith, of Hanover, read an able dissertation upon Suspended Animation, and Dr. S. B. How, of Manchester, a report on Surgery, giving a detailed account of several cases that had come under his observation.

At 2 p.m. the Society adjourned to the Phœnix Hotel to partake of the annual dinner, after which the *post-prandial* exercises were under the direction of Dr. F. A. Stillings, of Concord, who presided as anniversary chairman, and able and excellent responses were made to appropriate sentiments by the President, the Chaplain, Drs. Russell and Gay, of Massachusetts, Dr. Hill, of Dover, Dr. Fowler, of Bristol, and others.

At 4.30 p.m. the Society again assembled in the Hall, and the reading of papers was resumed. The Secretary read an essay on the Province of Medicine, by Dr. M. C. Dix, of Hinsdale, who was unable to be present; and Dr. F. A. Stilling, of Concord, gave an able paper on Melancholia and its Connection with Ancient and Modern Suicides. These papers were referred, without discussion, to the Committee on Publication.

The Committee on the time and place of holding the Semi-Annual Meeting reported, through Dr. A. H. Crosby, of Concord, that the inducements presented by the managers of the Pemigewassett House, at Plymouth, had been accepted, and the meeting was to be held in September, and that, on the second day, by reason of the liberal offer made by the managers, there would be an excursion for the profession and their families upon Lake Winnepesaukee. The report was accepted, and the Committee of Arrangements was ordered to invite the New Hampshire Pharmaceutical Society, the district medical societies of the State (and such of the profession in other States as could easily arrive at Plymouth in one day), to be present, with their wives, and enjoy, with the State Association, a social meeting, with a day of rest and recreation from the cares of professional life. Report accepted, and the Society adjourned until 8 P.M.

Evening Session.

This Session was mainly devoted to the report on Necrology, by Dr. Hill, of Dover, who reported the deaths of Dr. N. Tolles, of Claremont, Dr. D. E. Wells, of Hill, Drs. A. R. Dearborn and B. E. Harriman, of Concord, and Dr. A. C. Whipple, of Ashland. Appropriate obituary notices of the above were read by Dr. J. S. Swett, of Newport, Dr. H. B. Fowler, of Bristol, Drs. Cook, Crosby, and Conn, of Concord, which were accepted and referred.

The remainder of the evening session was devoted to the discussion of papers, and several interesting cases were reported. Dr. Russell, of Concord, reported a case of rheumatic pericarditis, in which the temperature was persistently high, 102° to 104°, and the respiration so much increased as to make it very difficult to count. The case being fatal, *post-mortem* showed that the plastic material effused upon the surface of the pericardium had become organized into growths resembling the fern in vegetable organization; and the lungs seemed to have suffered secondarily from the pressure of the over-worked central organ.

INGUINAL HERNIA—SUPPLEMENTARY SAC.

Dr. Crosby, of Concord, reported an operation for direct inguinal hernia, in which the strangulation had existed about seventy hours. The tumor was oblong but very hard. Upon cutting down, he exposed what looked like the hernial sac, and after nicking the edge of the ring, he attempted to reduce the mass, but failed. He then laid the sac open freely, releasing a considerable quantity of serum, and exposed a dark colored mass of omentum, which was enveloped in another sac. This contained very little, if any, fluid, and could not be reduced. The covering was, *apparently*, a true hernial sac, and this in turn was opened, and disclosed a mass of omentum, very dark in color, but not disintegrated at all. The ring was now touched for the third time with the hernial knife, the protruded mass gently restored to place, and the wound dressed in the usual manner. The knuckle of omentum probably broke down, as there was subsequently a profuse discharge of foul pus from the opening, and the man made a fair but slow recovery. The interesting point in the case was the existence of the supplementary sac, resembling, as it did, the true hernial covering. From its situation and size, it could not have been a hydrocele of the cord. Dr. Stillings stated that Gross had described a similar anomaly, but did not attempt to explain it.

Second Day.—Morning Session.

After the election of officers, and the dispatch of some routine business, a general discussion ensued upon various matters of practice.

SCARLET FEVER AND SMALL-POX.

Dr. Wheeler, of Pittsfield, reported a case in which a child, recently vaccinated, had incurred an attack of scarlatina, and the two diseases progressed simultaneously, resulting in death. The character of the rash was modified by the cow-pock.

Dr. Parsons, of Portsmouth, reported an epidemic of small-pox in his neighborhood, caused by a good-natured woman, who, having contracted the disease elsewhere, came home and distributed crusts from her pustules, with instructions to *vaccinate* themselves, and thus escape her malady.

MALIGNANT TUMOR OF THE BREAST.

Dr. Wheeler reported a case which had been seen the previous day by several members of the Society. A woman, aged about forty, whose mother died of schirrus breast, began to suffer three years ago with pain in the dorsal spine, which was treated as neuralgia, but never wholly relieved. Within a few months a "dimple" appeared under the breast, upon the inner side, near the sternum. At the base of this depression is an induration, the size of half a chestnut, firmly attached to the sternal end of the rib. There has been but little pain at this point, but there is a line from this to the spine which is tender upon pressure. The case was discussed by Drs. Howe, Parsons, Weymouth, Crosby, and others. While a majority thought it malignant, others regarded it as a neurosis simply, and suggested galvanism to establish the diagnosis, and, perhaps, cure it.

The delegates to Dartmouth Medical College, and to other State Medical Societies, made reports, and the secretaries of the several District Societies gave an abstract of the work of their respective associations.

The Auditors reported the Treasurer's account to be correct. All of which was accepted without discussion, and referred.

By special order, at nine o'clock, the following officers were elected. Also a council of twenty members and ten censors, as well as committees to report at the next annual meeting.

OFFICERS ELECTED.

President, Dr. G. P. Conn, Concord; *Vice-President*, Dr. H. B. Fowler. Bristol: *Treasurer*, Dr. L. B. How, Manchester; *Secretary*, Dr. M. W. Russell, Concord; *Anniversary Chairman*, Dr. C. A. Tufts, Dover.

Executive Committee, Drs. P. A. Stackpole, Dover; J. W. Parsons, Portsmouth; and A. H. Crosby, Concord.

The further discussion of papers and cases then took place, until adjournment at 12.30.

The next annual meeting will be held at Concord, on the third Tuesday of June, 1881.

Astrological Pathology.—Under this head the *Lancet* states that in the coming fall, the planets Jupiter, Saturn, Uranus, and Neptune will be in perihelion simultaneously. This has not happened before for more than eighteen hundred years. An Irish prophet asserts also that the "Star of Bethlehem" will make its appearance in the horizon during August. These celestial events are to usher in the disastrous outbreaks of many pestilences—a veritable saturnalia of death. We are to anticipate a recurrence of the terrible pestilences which concurred with the earlier years of the Christian era, and of which the recent irruptions of plague are the forerunners.

In view of this doleful prospect it is pleasant to feel that we have a National Board of Health, at any rate.

Correspondence.

"SANITARY ADMINISTRATION AND EPIDEMIC DISEASE."

To the Editor of The Medical Record.

Sir:—A paper bearing the above title appeared in the number of the Medical Record for June 26, 1880, and contains some statements which seem to me to require an answer.

The first part of the paper referred to, starts out with the assumption, that "disease, like its congener, pain, is not an evil," and lectures sanitarians for wasting their efforts in attempting to exterminate disease, when their efforts should be directed to remove the conditions which cause disease and death.

I think that this criticism of Prof. Lyman is hardly fair to sanitarians, for the great and ultimate object of all sanitary science is this very prevention and removal of the causes of disease.

Imperfect as our knowledge of the causes of many diseases still is, we have to thank, to a great extent, physicians interested in sanitary science for such information as we possess.

Numberless illustrations of the truth of this statement might be given, but I will only here mention the valuable information recently given by Dr. Thorn, of England, concerning the late outbreak of typhoid fever at Caterham, England, last year; also, the late interesting researches of Dr. Benjamin Browning, concerning the propagation and artificial production of diphtheria in man and inferior animals.

But to return to the first part of Dr. Lyman's statement, I venture to dispute in toto the proposition that disease and pain are not evils. It is, doubtless, perfectly true that man, like all other organic forms, is born to die, and the fact of his birth presupposes his death.

But death by disease, such as the physician has to deal with, is not the normal way in which life should gradually and painlessly terminate.

If every human being were born of perfectly healthy parents, and from the time of his birth were placed under proper sanitary and hygienic conditions, this life would end by a gradual and painless cessation of being.

Disease, in other words, is a result of a want of proper correspondence between the habits and mode of life of the individual and his environment; hence it is not in consonance with the normal law of nature, but antagonistic to it.

But a still more questionable statement is made by Dr. Lyman in the following words: "But if quarantine shall fail to keep out the infective agent, we must rely on local sanitation and personal hygiene, upon actual deportation of the movable population, and the most rapid possible diffusion of the disease, among those who elect to remain upon the infected spot, so that the epidemic period may be shortened and the number of acclimatized persons may be increased."

Farther on he says that "in proportion to the pandemicity and continuity of virulent diseases, will be the diminution of their danger."

While it is perfectly true that the cases found at the outbreak of an epidemic are generally more virulent and fatal than those found at a later period of the disease, yet it is absurdly incorrect to say that the general mortality from that disease is diminished by its diffusion among the population.

The history of all epidemics shows, I think, conclusively, that the fact is just the reverse of the statement made by Dr. Lyman.

The ratio of deaths to the number of cases is often diminished during the course of an epidemic, but the number of cases becomes so much greater that the mortality from the epidemic disease is increased.

Witness the epidemics of diphtheria, epidemic dysentery, scarlet fever, measles, etc., which have prevailed in our country during the present generation. Does Dr. Lyman mean to say that the mortality from these diseases was diminished by their spread in the community? Such a statement carries with it its own refutation.

This is also well seen in Great Britain, for nearly a century. Scarlet fever has been endemic therein, and has that fact diminished the mortality from scarlet fever in that country? By no means, it rages virulently to this very day, and it is estimated that from 60 to 70,000 persons died there from scarlet fever and its sequelæ, annually.

The following advice is given by Dr. Lyman concerning the prevention of epidemics: "The true way to prevent these revivals of epidemic disease is to cultivate its virus, and to maintain its presence in the community as carefully as we do in the case of small-pox."

This allusion to the use of vaccination for the prevention of small-pox is a very unfortunate one for the doctor's argument, for the fact is, we do not cultivate or maintain the presence of small-pox in the community by vaccination at all. The old and obsolete practice of inoculation did retain small-pox in the community, and for that very reason was abandoned.

Vaccinia, it is true, was and is produced from small-pox virus, but in passing through the changes it undergoes in the cow a new disease is produced, local and protective in its character, and which is quite different from variola.

But the cream of Dr. Lyman's article shows itself in a later paragraph, in which he says:

"By weeding out the feeble offspring of the community, the prevalence of epidemic disease is a constant source of vigor to the community."

In the language of the immortal "Boz," "here's richness for you."

In other words, we are advised to retain epidemics in our midst to kill off our weakly children. How does that sound when put down in plain English?

A much shorter and more effective method would be to do as the ancient Spartans did, namely, expose them to wild beasts, or drown them as is now done to female infants in China.

I would like to ask, in all seriousness, where can be found any proofs of such statements? How is it possible that the destruction of thousands of lives, and the mutilation of other thousands by lesions of important organs, which are the well known results of epidemics of scarlet fever and other like diseases, can in any way affect favorably the human race.

Has not history shown, by irrefragable proofs, that the vigor and length of life in modern times has increased, whilst many of the epidemic diseases, such as the plague, typhus fever, small-pox, etc., have almost disappeared from the world's history?

The hands of the men of our age are too large to grasp fittingly the sword-handles of our Norman ancestors, and our bodies too large to be covered by their armor.

Robert Reyburn, M.D.

Washington, D. C.

ASBESTOS ROOFING FELT AS A MATERIAL FOR SPLINTS.

To the Editor of The Medical Record.

Sir:—I wish to call the attention of the profession to the great advantages of asbestos roofing felt as a material for plastic splints and other moulded apparatus. I have for some considerable time made use of this article in my practice, and have found it preferable to any other material yet proposed for such uses. A brief statement of its qualities will show how greatly it excels pasteboard, leather, starch, plaster, or gutta-percha.

1st.—It is rendered perfectly soft and flexible by brief immersion in water, of a temperature which can be borne by the hand without difficulty.

2d.—It retains its plasticity quite long enough to allow of careful adaptation, while its stiffness is instantly restored by a dash of cold water.

3d.—While soft it does not change dimensions, as is so often, and annoyingly, the case with gutta-percha.

4th.—It remains unchanged after indefinite exposure to the heat and moisture of the body. Nor is it affected by any of the ordinary lotions, etc., applied in cases of wound or fracture.

5th.—It is perfectly antiseptic on account of the coal tar with which it is saturated, a quality which of itself would especially commend the use of the article in all cases of compound fracture.

6th.—It is so cheap that its cost is hardly worth estimating, even in large institutions.

The felt which I have used is manufactured by Johns & Co., New York. It is, however, probable that there are other articles of the kind in the market, which will be found equally available.

Stuart Eldridge, M.D.,
Surgeon to General Hospital, Yokohama.

Yokohama, Japan.

PERSISTENT PRIAPISM.

To the Editor of The Medical Record.

Sir:—The case of persistent priapism reported by Dr. G. L. Peabody, in the *N. Y. Medical Journal*, May, 1880, and copied into the Record of July 3d, brings to mind a similar case which came under the writer's observation in September, 1870, notes of which have been preserved. The subject was an American, a farmer's boy, nineteen years old, who, for several years previous to the attack, had exhibited the characteristics of paludal cachexia, and had been treated for the same. He had also received treatment for caries of the tarsal bones of the left foot. The priapism began on the 8th of September and continued nearly five weeks. During the first twenty days of the attack, pain and discomfort were excessive, being precisely like that experienced in gonorrhœal *chordée*. The temperature and pulse were both largely increased, especially at night, when the pain was also more severe. Urination was frequent, but unobstructed, and there was a copious urinary deposit of yellowish colored sand, which, on examination, was found to consist of uric acid crystals. The blood was not examined, but symptoms and appearances of leucocythæmia were all present. The spleen was greatly enlarged, and the cervical glands were prominent and indurated. The skin was pale and waxy; the muscles of his legs and arms were weak and trembling; palpitations were complained of, but no abnormal heart-sounds were noticed. Epistaxis occurred twice during the continuance of the priapism. There was considerable bronchial catarrh and cough. The principal remedies used were quinine and iron, with anodynes to relieve pain. Cold applications, locally, increased the distress. Warm fomentations afforded slight relief. At the end of the fifth week the organ had about regained its natural size, and the patient's general condition had somewhat improved. The leucocythæmia was not cured, however, and about eleven months afterward the patient succumbed to its effects.

If Dr. Peabody's case is the seventh recorded instance of persistent priapism occurring in leucocythæmia, this one may, perhaps, be numbered the eighth.

Very truly yours,
G. F. Wetherell, M.D.

Lyons, Iowa.

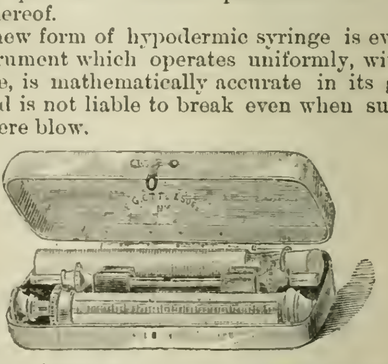
New Instruments.

THE CELLULOID HYPODERMIC SYRINGE.

The Celluloid hypodermic syringe, constructed entirely of celluloid, supplies an article which is perfect of its kind. The barrel is clear and transparent, and thus embodies all the good qualities of glass in this connection; but, being made of celluloid, it possesses the toughness and strength of this material, and cannot be broken even by the roughest usage. In addition to its singular strength and durability, the celluloid syringe avoids in its construction the inaccuracies and other disadvantages found in the graduation and operation of even the best glass syringes, because of the difficulty of obtaining a perfectly true cylindrical bore in the glass tubes.

The transparent celluloid syringe barrels are manufactured upon a mandrel. This insures mathematical exactness and uniformity in the bore from end to end, and permits the utmost precision in the graduation thereof.

The new form of hypodermic syringe is evidently an instrument which operates uniformly, with perfect ease, is mathematically accurate in its graduation, and is not liable to break even when subjected to a severe blow.



These syringes are put up in handsome celluloid cases, which are themselves worthy of notice. They are very strong; are always clean and neat in appearance; are not easily scratched or defaced, and maintain a beautiful polish. They are made in various colors, with rounded corners, so as not to catch or wear the pocket, and are fitted with nickel-plated catches and hinges.

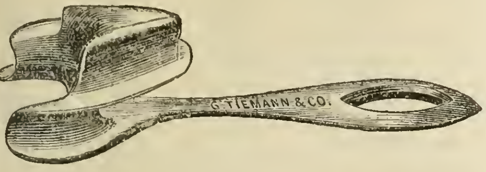
Every syringe is warranted as to strength and accuracy of graduation, and the manufacturers, F. G. Otto & Sons, guarantee to replace any celluloid hypodermic syringe, in which the barrel is broken by a fall from any height, or by other similar accidental shock or blow.

COMBINED MOUTH-GAG AND CHEEK RETRACTOR.

By J. O. ROE, M.D.,

ROCHESTER, N. Y.

The following cut represents a modification of the ordinary cheek retractor of Luer, by which it is at the same time made to answer the purpose of a most excellent mouth-gag.



The improvement consists in the addition of a triangular or wedge-shaped block to the external surface of the cheek-retracting portion of the instrument, as shown in the illustration, so that on introducing the instrument as a cheek-retractor, the wedge-shaped portion passes in between the teeth and thus distends the jaws.

This simple instrument I have found to be exceedingly convenient in operations about the mouth and throat, where the mouth and jaws are required to be distended and held by a mouth-gag. In several respects it has advantages over the metallic gags. It gives a greater amount of oral room, as it is only necessary to introduce a gag on one side, a simple retractor on the other; thus both sides of the mouth or cheeks are drawn back to their greatest extent, leaving the whole mouth free and clear.

They can be readily made self-retaining by simply passing a cord through the hole in the handles and tying it behind the head.

Another advantage which it is found to possess, is the ease with which it can be retained during protracted operations. In those gags where the bearing is on the anterior portion of the jaws, in distending the mouth widely it often becomes painful and distressing to the patient unless under an anæsthetic; but with this form the bearing directly antagonizes the masseter muscles, and affords direct support for the distended jaws.

In operations where the tongue must be held down, as in staphylorraphy and uraniscoplasty, it can be easily done by the Sass depressor, or the very convenient self-retaining tongue-depressor of Dr. Goodwillie.

In operations on children, it is very convenient, and being made of wood is less formidable in appearance than a metallic instrument.

This gag may also be used by dentists in many cases of operations, with not only facility to themselves, but with decided relief to their patients.

The instrument can be made of rubber, wood, or any suitable material.

If made of box-wood, as cheek-retractors usually are, it is best to have the gag portion made of some softer wood or rubber, which is not so severe on the teeth, and which may be fastened to the retractor afterward.

They may be made of different sizes to fit the various-sized mouths, or the gag portion, if made detachable, can be made of any size to meet the requirements of any case.

The instrument is manufactured by Geo. Tiemann & Co., New York.

A NEW FORCEPS FOR HOLDING CURVED SURGICAL NEEDLES.

By J. T. MATHIS, M.D.,

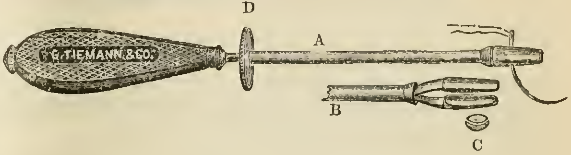
AUSTIN, TEXAS.

It has long been a desideratum in the field of surgery to have a needle-holder which will hold the needle firmly, and, at the same time, prevent it from turning and cause the operator to lose his control of its direction.

That desideratum is attained in a needle-forceps having one concave and one convex jaw. The concavity is designed to fit the convexity of the curve of the needle, while the convex mandible ought to fit the concavity of the curve of the needle.

There is nothing in the instrument claimed as new except the arrangement of the jaws. The depth of the concavity of the female blade constitutes the lever which prevents the needle from turning. The needle cannot turn.

When properly adjusted in the forceps, it need not break. The eye of the needle should not be held between the jaws.



In the figure, A shows the whole instrument closed, holding the needle for use in the left hand. The forceps may be used in either hand.

B shows the jaws open. They are closed, fastening the needle, and opened, releasing it, by means of the cylindrical slide moved by the fingers acting upon the button D.

C represents a transverse section of the closed jaws, showing the space between them an arc of a circle, as a receptacle for the needle. This arc belongs to the same circle as the needle to which it is adapted.

The only question to be settled by the surgeon in making his order for forceps pertains to the sizes of the needles which he may wish to use. The proximal end of the jaws is suited to the largest needle in the list, and the distal end to the smallest. The intermediate space is adapted to all the intervening sizes. But little practice is necessary to enable the surgeon to adjust any needle in his list to that part of the jaws to which its size is fitted. I have also ordered Geo. Tiemann & Co., my instrument makers, at 67 Chatham St., New York City, to adjust the same jaws to the principal mechanical arrangements of Dr. Sands's forceps, and also to another mechanical arrangement which may be presented to the surgical profession at no distant day.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 25, 1880, *to August* 7, 1880.

Fryer, B. E., Major and Surgeon. Granted leave of absence for twenty days. S. O. 161, Department of the Missouri, July 26, 1880.

Webster, Warren, Major and Surgeon. His leave of absence extended one month, provided he furnishes satisfactory medical attendance during his absence. S. O. 124, Department of the East, July 27, 1880.

King, Wm. H., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for an extension of three months, on surgeon's certificate of disability. S. O. 87, Department of Dakota, July 21, 1880.

COMEGYS, E. T., Captain and Assistant Surgeon. So much of S. O. 135, C. S., from these headquarters, granting him leave of absence on surgeon's certificate of disability, is revoked. S. O. 144, Department of Texas, July 19, 1880.

BENHAM, R. B., First Lieutenant and Assistant Surgeon. Having reported at these headquarters, is assigned to duty (temporary) at Fort Snelling, Minn. S. O. 87, C. S., Department of Dakota.

GORGAS, W. C., First Lieutenant and Assistant Surgeon. To report to the commanding officer, Fort Clark, Texas, for duty. S. O. 147, Department of Texas, July 23, 1880.

STRONG, NORTON, First Lieutenant and Assistant Surgeon. Assigned to temporary duty at Fort Douglas, Utah. S. O. 70, Department of the Platte, July 31, 1880.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending August 7, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
July 31, 1880.	0	12	22	5	16	46	0	0
Aug. 7, 1880.	0	15	20	1	11	30	0	0

THE MEDICAL DEPARTMENT OF THE ARMY.—Four years ago the Medical Department was reorganized and reduced from 209 to 192 officers of all grades, twenty-five assistant surgeons with the rank of first lieutenant and four storekeepers with the rank of captain being deducted, and eight colonels and four lieutenant-colonels added, making a net decrease of seventeen. When the reorganization was carried out there were half a score of vacancies for assistant surgeons, notwithstanding the reduction. The annual appointments since then have barely equalled the annual casualties, and the reduced legal complement of this class of officers has not yet been completed. At present there are nine vacancies, with a prospect of others as soon as certain incapacitated officers shall have been retired from active service. One of the vacancies has existed since March, 1879, and the others for periods varying from two months to twelve.

Some comment has been aroused by this state of things. It is not, however, very hard to be accounted for. The standard of admission to the service is very high. In order to prepare himself for it, the student must, generally, go through a special course of cramming, which involves money and much hard work. Few of the best men care to enter a service which takes away their personal independence, and which offers very slow promotion, a comparatively small income and scarcely any chance of medical or surgical distinction. Our Army and Navy Medical Service has had much less difficulty in getting good men than has been the case in England, where the medical education is not thorough.

THE EFFECT OF HEAT UPON THE DEATH-RATE.—The two very hot spells which this city endured in June and July, have led to a comparison of statistics, which illustrate very well the effect of heat upon the mortality, especially among the children. We present the following tables:

		Highest No. of Deaths.	Mean Temperature, Fahr.	Mean Humidity.
1870..........	July 22	1,010	82.31	54
1871..........	July 15	822	79.5	62
1872..........	July 6	1.591	83.9	75
1873..........	July 19	917	72.8	65
1874..........	July 25	861	74.8	56
1875	July 24	939	72.6	69
1876..........	July 15	1,293	83.9	68
1877..........	July 14	825	74.0	74
1878..........	July 13	741	77.8	70
1879..........	July 19	772	76.3	64

The total number of deaths, by weeks, for June, 1879 and 1880, has been as follows:

1880.		1879.	
June 5............	501	June 7............	490
June 12...........	479	June 14...........	441
June 19...........	707	June 21...........	473
June 26...........	1,038	June 28...........	562
Total.........	2,725	Total.........	1,966

Of children under one year of age the number is as given below, showing the rate to have nearly doubled this year:

1880.		1879.	
June 5....... ...	112	June 7......... ..	101
June 12...........	144	June 14...........	97
June 19...........	278	June 21...........	156
June 26...........	529	June 28...........	217
Total.........	1,063	Total.........	571

VIRCHOW has been returned to the German Parliament for the second electoral district of Berlin, as the candidate of the United Liberals.

SEVENTH ANNUAL CONFERENCE OF CHARITIES AND CORRECTION met at Cleveland, June 29th, 30th, July 1st and 2d. Gen. Brinkerhoff, President. A large number of delegates, representing sixteen States, was present. New York was represented by Dr. Chas. S. Hoyt, of Albany, Secretary of the State Board of Charities and Correction; Dr. David Rogers, of Queens County Insane Asylum; Dr. John G. Shaw, of Flatbush Insane Asylum; Drs. Seguin, Beard, and others.

After the usual introductory speeches, the president delivered his annual address. This was an admirable *résumé* of the condition and methods of working of the various charitable and correctional institutions of each State. It will form a valuable mine of information upon the subject. Of New York he said, "she is in the front rank in charitable and correctional institutions, and in some respects is in advance of all others. Her Reformatory at Elmira is in most respects the best model for prison management in America, and her Asylum for Chronic Insane, in a large degree, has solved the problem of economy and comfort combined in the care of that unfortunate class.

On the second day, Mr. F. B. Sanborn was elected president. Various papers were read in regard to the treatment of juvenile offenders, the care of delinquent children, and the subject of immigration. The most notable address was by Mr. Henry W. Lord, Secretary of the Michigan Board of Charities, "On Prisons and Prison Discipline." Most of the address was devoted to an argument against capital punishment. The paper made a marked impression.

The third day was devoted to the discussion of the care of the insane. The report of the Committee on Insanity was read by Dr. J. P. Bancroft, Chairman. This was followed by a paper by Dr. R. Gundry, Superintendent of the Maryland State Asylum, "On the Care of the Insane." In these papers, and in the discussion following them, opinions favorable to non-restraint and to the greater occupation of patients were expressed. Dr. John G. Shaw, of Brooklyn, read a very candid and practical paper "On the Value of Non-restraint in Treating the Insane." He was followed by Dr. E. C. Seguin, who spoke on the right of the insane to liberty. A paper by Dr. Nathan Allen, "On the Supervision of Asylums," was read by Miss A. A. Chevalier. Dr. Geo. M. Beard made some remarks on the need of an association for the protection of the insane. A letter from Dr. Nathan Allen, of Massachusetts, was read, in which he expressed his hearty sympathy with the project of forming such an association.

Resolutions were unanimously adopted, recommending that greater facilities be furnished the insane for employment and occupation; condemning the architectural construction of many of the asylums on the score of their cost and inadequacy to meet the best needs of the inmates; endorsing the plan of separating in most cases the chronic from the acute insane; and recommending that consulting boards of physicians be attached to insane asylums.

A National Association for the Protection of the Insane was organized with the following officers: President, H. B. Wilbur, of Syracuse, N. Y.; Vice-President, Nathan Allen, of Lowell, Mass; Treasurer, Geo. M. Beard, New York, and a council of fifteen, embracing a number of physicians, among whom are Dr. Mary Putnam-Jacobi, Dr. John G. Shaw, and Dr. Seybura, of New York. The Association will meet in New York, the last week of next September, to perfect its organization.

The remainder of the session was occupied with matters having but little medical interest.

Fees for Testifying as Experts.—The South Carolina Legislature, at the instance of the Abbeville Medical Society, has passed a law giving physicians $10 for testifying as experts in any medical case, also the mileage and per diem pay accorded to ordinary witnesses.

The American Medical College Association and the American Medical Colleges.—From the report of the Committee of the American College Association, we learn that sixty-three regular medical colleges now exist in the United States, of these, twenty-eight publicly conform to all the requirements for active membership in the American Medical College Association. Thirty-five do not thus conform, of which number, sixteen fail apparently from oversight only. Six of the colleges do not require evidence of three years' study as a requisite for graduation. Two colleges do not require attendance upon more than one course of lectures. The regular term of five colleges is less than twenty weeks. Four colleges grant *ad eundem* degrees on a simple examination in the practical branches. Three colleges hold lectures in the evening.

The American Medical College Association now includes thirty-one active members. During the past year three colleges resigned, viz.: The Medical Department of the University of Vermont; The College of Physicians and Surgeons, of New York, and The Bellevue Hospital Medical College. Five colleges were admitted to active membership, viz.: The Cincinnati College of Medicine and Surgery, Medical College of Indiana, Nashville Medical College, Savannah Medical College, St. Joseph Hospital Medical College, and Kentucky School of Medicine.

The Association claims that, as the result of its four years' work, it has, (1.) Greatly diminished the number of diplomas that are bestowed without thorough study and examination. (2.) It has diminished the number of "dead-heads" in the several medical classes. (3). It has increased the revenues of the colleges as a whole. (4.) It has greatly promoted uniformity in medical training and in requirements for graduation. (5.) Its standard has been formally adopted by nearly all the colleges that started during its existence. (6.) All the two-term (in one year) schools have disappeared, and with but two exceptions (the University of Virginia and the Harvard Medical School), it is impossible for a medical student to complete his college work within one year, at any regular college or colleges of the United States.

The Association, besides voting that attendance on three full courses of lectures be made a requisite for graduation, passed an amendment accepting a certificate of two years' study such as is given at Cornell, as an equivalent to the first year's course. The proposed extension of the course to three years is to be enforced after the session of 1882–3.

Dr. E. C. Wendt, of this city, has been appointed to the Chair of Comparative Anatomy, Embryology, etc., in the Columbia Veterinary College.

Dr. Tanner's Fast was completed at noon, August 7th. Dr. T. suffered a great deal from attacks of retching and vomiting during the last few days, and he could not have endured much longer. His pulse, temperature, and respiration continued about normal, and his mental faculties were not impaired. His weight at the end of the fast was 121½ pounds, a loss, during the entire forty days, of exactly thirty-six pounds. As soon as the fast was ended, he drank about seven ounces of milk and ate some fruit, and during the afternoon and evening he repeatedly took nourishment, among other things two half-pounds of steak. He has continued since to eat and drink largely and frequently, his diet-list including beef-steak, potatoes, beef-tea, oysters, boiled eggs, crackers, fruit, milk, ale, and wine. Not the slightest trace of nausea or sickness has appeared since the close of the fast, and the doctor is in excellent spirits and is gaining strength rapidly. His weight, at noon, August 9th, forty-eight hours after the close of the fast, was 132½ pounds.

A New Dispensary for Women and Children was opened at Harlem, July 12th. The house physician is a woman. A majority of the medical staff are also female physicians.

The Apostle of Cremation, Giovanni Apolli, was incinerated at Milan, recently, with much ceremony. It was the sixty-eighth case of cremation at Milan in the last four years.

Dr. J. J. Woodward on the Pathological Histology of Yellow Fever.—In a supplement to the Bulletin of the National Board of Health for April 24th, Dr. J. J. Woodward has presented the results of his study of the pathological specimens brought from Havana last summer by the Yellow Fever Commission.

Dr. Paul Broca, Physician and Senator.—Dr. Paul Broca died recently at Paris. He was born at Sainte-Foy-la-Grande (Gironde), June 28, 1824, studied medicine under his father, who was a distinguished physician, graduated at an early age from the Paris Faculté de Médecine, and became an assistant in the metropolitan hospitals in 1844. He soon gained prizes for skill, became a demonstrator of anatomy and prosector, and graduated as M.D. in 1849. He then pursued a course of surgery at the École Pratique, published in 1852 a treatise on the "Pathological Anatomy of Cancer," took his surgical degree in 1853, was successively surgeon of the Bicêtre, the Salpêtrière, the Saint-Antoine and the Pitié hospitals, and became professor of surgical clinics at the latter institution. He was one of the earliest surgeons in France to make a specialty of the science now known as anthropology, and it was largely through his efforts that the flourishing French Society of Anthropology was founded. He was long its secretary-general and the director of the School of Anthropology, as well as of the Anthropological Laboratory at the École des Hautes Études. He was also a prominent member of the Surgical, Biological, Philomathic and Anatomical societies, and an honorary or corresponding member of the leading scientific societies of Europe and America. He was elected a member of the Imperial Academy of Medicine, July 26, 1866, and was decorated with the Cross of the Legion of Honor in 1868. He published treatises on "Abdominal Hernia" (1853), on "Aneurisms" (1856), on "Fractures and Osseous Regeneration" (1859), on "Surgical Hypnotic Anaesthesia" (1859), on "Chronic Abscess of the Medullary Canal" (1859), on "Resuscitating Animals" (1860), on "Animal Hybridity in General, and Human Hybridity in Particular" (1860), a "Treatise on Tumors" (1865), and was author, along with C. Bonamy, Emile Beau, and L. Hirschfeld, of a magnificent "Descriptive Atlas of the Anatomy of the Human Body (1856 *et seq.*). In the line of anthropological researches his chief publications were: "General Instructions for Anthropological Researches" (1865), "The Physical Character of Prehistoric Man" (1868), The "Comparative Anatomy of Man and the Primates" (1869), and the preface to Dr. Paul Topinard's popular work on "Anthropology" (1876). Dr. Broca was the president of the Congress of Anthropology held at the Trocadero, Paris, in 1878, in connection with the Universal Exposition of that year. He was the earliest prominent French physician to accept the Darwinian doctrines of development, of which he became the most noted representative in his country. In February, 1880, he was elected a life senator in place of Count Montalivet, after having been unsuccessful in one ballot, on account of his Darwinian doctrines. He was a consistent supporter of moderate republican doctrines.

"Science" is the name of a new weekly journal, exclusively devoted to chronicling the progress of science, and to discussing its problems. It is intended to take such a place in this country as *Nature* holds in England. The editor is Mr. John Michels, and he is supported by a numerous corps of associates, including several members of the medical profession in this city, Boston, and Washington. The first number is a good one, and gives a fair promise of the success of the enterprise.

Trephining.—In the report of the two cases of trephining published in a recent number, the name of the author should have been Dr. H. R. Kelly.

A Gorilla Cadaver—Dr. Thos. G. Morton, of the Pennsylvania Hospital, has recently received from Africa a large female gorilla, preserved in alcohol. The animal is about four and a half feet high, and, as it lies in a tank covered with a glass top, has much the appearance of a human being. The similarity is greatly increased by the fact that the dark epidermis and long hair with which it was covered, have been almost entirely removed by maceration in the fluid. A few days ago it was removed to the garden of the hospital and photographed in the erect position. It will probably be studied and kept in one of the scientific museums of Philadelphia.

Plans for Healthy Tenements.—By invitation of the City Board of Health, a number of leading plumbers, architects and others interested in the construction of dwelling-houses, met in the office of the Health Board, July 8th. A number of sanitary points were discussed. They recommended in general that better work and better workmen be employed in plumbing houses and in the construction of sewers. They further recommended air- and water-tight joints and traps; also that sewers and soil-pipes be made of iron; that traps be ventilated, and that the systematic use of deodorizers be discouraged as tending to conceal without destroying foul gases. There was a difference of opinion as to whether traps should be placed between houses and street sewers.

The Sanitary Inspections of the Tenement-Houses.—Fifty inspectors began their work on July 1st, and by July 3d had inspected 2,873 houses, had visited 18,953 families, and prescribed for 607 children, besides distributing tickets to the Floating Hospital. The number of families visited per week is usually about 50,000.

The Night Medical Service.—At a meeting of the City Board of Health, July 27th, the registrar of vital statistics was directed to appoint an executive officer, to be selected from the clerks or other employés of the sanitary bureau of records, to serve without any additional compensation. Casper Golderman was appointed cashier, and requisitions were received for books and stationery for the service.

The State Board of Health has begun the exercises of its functions by declaring a pest-hole at Buffalo a public nuisance, and ordering it to be abated. Their attention has also been called to the guano manufactories and other sources of stenches in Long Island City.

SUPPURATIVE DISEASE OF THE ANKLE IN CHILDREN AND YOUNG ADULTS.*

A Record of Twenty-six Cases.

By THOMAS E. SATTERTHWAITE, M.D.,
NEW YORK CITY.

Soon after the Therapeutical Society of this city undertook an inquiry into the treatment of carious ankles, so many records of good results were placed in the hands of the Surgical Committee, that it was thought desirable to report in brief a summary of the conclusions that had been reached. Accordingly, at the ninth regular meeting of the Society, Dec. 19, 1879, this was done by the chairman of the committee. A synopsis was then given of twenty-four cases, which demonstrated clearly that the expectant plan pursued in most instances was competent alone to effect a satisfactory cure, with a very inconsiderable loss of function and within a reasonable time. These conclusions have since been further sustained by Dr. V. P. Gibney, in an elaborate paper,† wherein he reviews the final results in thirty cases that came under his own observation, fourteen of which are additional to the sixteen he has contributed to this present report. Dr. G. calls attention to a fact which has more recently been recognized by surgeons and orthopedists on both sides of the water, viz.: that many children annually suffer amputation of the foot, when, under conservative treatment, the member could have been saved. He further boldly states that neither excisions, partial or complete, nor other operative procedures, offer advantages superior to the expectant plan, which at once assures a more perfect result than any known to the profession. The expectant method which Dr. Gibney employs he defines in the words of the preliminary report. They are as follows: "If the joint is inflamed, entire rest is ordered; if abscess form, it is opened; if loose bone be detected, it is simply removed, as if it were a foreign body interfering with the process of healing; if in the further progress of the case malposition of the parts is found, a support or brace is given to rectify the deformity." Attention to the general health is also imperative, as may naturally be inferred. This method is simply one that addresses itself to immediate symptoms and recognizes any treatment that would suggest itself to a practical surgeon or orthopedist, provided only he does not practise chiselling (gouging), excision, setoning, or amputation, all of which may properly be regarded as operations of a systematic character.

It may not be amiss to state that the details of the cases in the hands of the committee have been most complete, and comprise a fund of great interest and value. The practical character of the report, however, precludes even a synopsis and much less an enumeration of all these points. It may be interesting to know that the number of affected males and females was equal, also that the majority (11) were attacked between the ages of six and thirteen. Under six there were eight, while over thirteen and under seventeen (the age of the eldest) there were seven.

One always approaches the etiology of a disease with caution. This should be particularly true in this affection, as it is a matter which is capable of giving rise to as great a diversity of opinion as morbus coxarius or Pott's disease. With a large class of people it is much more satisfactory to connect a disease with some well-defined cause, such as a fall, blow, or a sprain which the person had experienced at some previous period, even if the injury was trivial and had almost been forgotten. So much weight is apt to be placed upon such statements, that the personal and family history are not investigated with a proper amount of care, and the presence of a marked cachexia are not distinctly realized. In the present instance these remarks do not apply, because inquiry was directed into both conditions with equal closeness. But, in order to weigh each assumed factor properly against the other, *i. e.*, traumatism against a constitutional infection, we have been careful to institute a comparison only in those cases where a positive or negative statement was obtained on each point. Of these cases (sixteen), it appears that in only four there was an alleged injury without the suspicion of blood disease, but in five others the two were associated together. On the other hand, a cachexia without traumatism was noted in five. In the two remaining there was positively no record of an injury, and the personal and family history was excellent—an interesting circumstance, suggesting that there may be causes apart from a traumatism or cachexia. Not the least remarkable of the conclusions is that in thirteen the bone was thought to be the point from which the disease originated. In only two children were the soft parts first invaded. The extent of the bone-lesion is a matter that unfortunately we have no means of deciding, except where a systematic operation has been performed, or at a post-mortem examination; but to this matter allusion will again be made. It was a matter of less difficulty to determine the duration of suppuration, and this introduces another important but incidental consideration. In two instances suppuration did not exist, and the patients experienced a satisfactory cure. The explanation is as follows: caries, it is well known, sometimes persists for a time and then undergoes spontaneous resolution; or, in other words, a certain amount of disorganization may go on in a joint, and yet no discharge take place at any time. The pulpy material which takes its origin from the diseased bone and gives to the hand the "cushiony" feel when the opposing bone-surfaces are pressed together, is in part absorbed and in part converted into a fibroid tissue, which acts as a substitute for the synovial sac and its contained fluid.

An additional reason for regarding such cases as true examples of caries lies in the fact that the usual symptoms which invariably precede caries were present.

In these same sixteen cases the duration of discharge varied between four or five months and five and a half years.

A relapse in the last instance caused the unusually prolonged period of suppuration. In the majority it did not exceed one year.

In coming to the comparison between a variety of methods a very large amount of material is obviously necessary before we can obtain results of any practical value. The reasons are obviously the same that are applicable to any form of treatment, medical or surgical. One attack may be very mild and almost any well-conceived plan will accomplish a favorable issue, while on the other hand the extent of disease may be so great that nothing short of amputation will offer the least hope. First of all, then, we inquire the amount of bone-lesion; to this subject attention has already been directed. We may usually form a fairly accurate opinion from the number of sinuses and their situation; but even then it is notorious, that if we have an opportunity to make a manual examination, as after an amputation, the number of bones attacked is always greater than appeared probable at first.

---

* Final Report of the Surgical Committee of the Therapeutical Society on this topic.—T. E. S., Chairman of the Surgical Committee.

† Caries of the Ankle in Children, etc.: American Journal of Obstetrics and Diseases of Women and Children, April, 1880.

Then again, the disease may be limited to one or two bones which do not enter into the tibio-tarsal or medio-tarsal articulations. The result in such cases, when favorable, may seem perfect, because these important centres of motion have not been molested; on the other hand, a small focus of disease, involving these joints, will almost certainly diminish their function, even though a cure is obtained and lameness is not appreciated. Practically speaking, a cure means a useful joint, where all inflammatory conditions are at an end and the patient is able to use it in his daily avocations. The expectant method, chiselling, setoning, and excision, are all capable of accomplishing this object; but, for the reasons already mentioned, a comparison between them is practically impossible. Thus, Case XIX. was a more severe one than any that was successful under the purely expectant plan; and Case XXV. was one still more severe, involving the bones of the leg, tarsus, and metatarsus, and it is hardly likely that anything short of amputation would have been advisable.

The success of the expectant plan may be seen by its result in the cases where it was tried. Thus, in a total of sixteen, useful joints were obtained in fourteen, the average duration of treatment being two and one-half years, while there were only two failures. In one case the disease was of great severity, and the child died of exhaustive fever from prolonged suppuration; the other submitted to chiselling, and subsequently, excision. Gouging or chiselling was practised in five cases in conjunction with other methods, and gave a useful foot in three of them, one in the remarkably short space of four or five months. This period, which represents the entire duration of the disease, is the shortest of any, but left the child with a slight valgus, and it is the more remarkable as both ankles were involved. As opposed to such rapid cures, it may be questioned whether it is well to anticipate nature in her efforts at recuperation, for it is seen that the most perfect final results are those which nature has accomplished unaided. In place of the carious bone she deposits subperiosteally new material, which, gradually encroaching upon the disease. is ready to supplant it when the process of removal has been completed. Nor is the excision, complete or partial, always successful in arresting the carious process. The exfoliation often continues for months and years, and even occasionally seems to set up new disease manifestations of more rapid and dangerous character. This much may be said of the expectant method. In children and adults under fifteen years of age it is capable, in almost every instance, of saving the foot from amputation, and even excision, partial or complete. Further statistics will be necessary to show that it is slower than other methods, while, if successful, it affords a better result than any.

Though the normal mobility and size of the affected limb is scarcely regained, at least in early life, the disproportion is lessened with growing years, and the diminished motion at one joint is counterbalanced by increased mobility at another. Lameness is therefore seldom seen. The utility of the part is such that the patients may be reasonably sure of their ability to lead an active life without making use of any artificial support. In view of the facts, the deduction is very natural that surgeons, in these cases, should refrain from special operative procedures until the expectant method has had a thorough and prolonged trial.

Case I. (Dr. V. P. Gibney.)—About the first of February, 1870, a boy, eight years old, began to complain of pain and tenderness in his right ankle. The symptoms came on suddenly, and were thought to have been caused by an injury, the precise nature of which was not remembered. Inquiry also failed to discover any constitutional taint, whether inherited or acquired, nor could it be ascertained whether the disease originated in the bony or soft parts. The symptoms gradually progressed in severity, and on February 9, 1871, measurements showed that the right ankle was much enlarged (circumference over malleoli: right, 7¼ inches; left, 6⅞ inches), while the calf was correspondingly atrophied (circumference of right, 7¾ inches; of left, 8¾ inches). The other indications of chronic ankle-joint disease, such as puffiness, tenderness, obliteration of normal contour, and muscular rigidity, were well marked. It was observed, however, that when the opposing diseased joint-surfaces were brought together no sensitiveness was felt. On May 9, 1872, after the disease had continued more than two years, an abscess burst over the internal malleolus, and a sinus resulted. The discharge persisted for eight months, terminating in January, 1873. During all this time the treatment was expectant. On April 18, 1873, the child was discharged, and a record made in the hospital case-book states that he stood squarely on both feet, walking and running with perfect ease. Close observation was required to detect any limp. On manual examination there was found a slight anchylosis of the tibio-tarsal joint, but it was not tender on rough handling. Still, after excessive walking, the child complained of a little pain. The atrophy of the calf previously noted was still evident, the right measuring only 10¼ inches, the left 11½. Though the difference in measurement was but a trifle more in favor of the diseased limb than at the previous examination, relatively the improvement was marked, as the limb had increased much in size. The right ankle now was less in circumference than at the previous measurement (over malleoli: right, 6¾ inches; left, 7¼ inches). Length of right foot, 9½ inches; left, 10 inches. No shortening of the limb.

The foot can be flexed, etc., a trifle beyond 90°, but not to the normal. In extending, the os calcis moves perceptibly, while the point of the foot comes down almost equally with the other. Inverts and everts foot equally with the sound side. During the succeeding twelve months the patient led an active life and was free from pain, but it is said that subsequently he was tenotomized in the plantar region at a surgical clinic of this city. There is no scar indicating the site of the operation. The patient is now working in a piano factory.

The caries involved the lower epiphysis of the tibia, and probably the astragalus and scaphoid.

Case II. (Dr. V. P. Gibney.)—A little girl, eleven years old, of debilitated habit, after an attack of measles, but free from constitutional taint, unless possibly of a phthisical nature, on her maternal side, exhibited signs of joint-affection in December, 1869. There was no history of a previous injury. In the following month decided lameness was apparent, and the swelling had increased. On manual examination (April 4, 1880) the motion of the parts was resisted by muscular action. Contour was effaced, and the tissues had a pulpy feel and were inflamed, though not very tender. The bone was regarded as the primary seat of the trouble. Nocturnal pain was never present, nor did an abscess form at any time. The measurements at this time were as follows: circumference of right (diseased) calf, 7½ inches; of left, 9½ inches. A line passed around the malleoli showed that there was no difference between them. Over heel and instep the right measured 9, and the left 9¼ inches.

At the date of her discharge (April 30, 1873) flexion could be carried beyond 90°; extension, however, was not quite perfect; there was more than half the inversion of the other foot. She was in fair health, but walked with a slight halt; yet the ankle appeared normal and gave no evidence of pain, even after pretty rough handling. The treatment included the use of leeches, rest during exacerbations, moderate exercise at intervals, tonics alternating with cod-liver oil, massage, etc. A light support was subsequently put in use (expectant treatment). On final examination (Dec. 3, 1879) she was found to walk without lameness, though after excessive exercise there was a perceptible halt in the gait. A little grating, regarded as cartilaginous, was also detected at the tibio-tarsal articulation. Measurements: circumference of calf, right (diseased), 11 inches; left (sound), 12½ inches; length of right foot, 8¾ inches; of left, 9½ inches. The patient is now living at service, and her foot does not prevent her from doing ordinary work. It is not tender on pressure.

Case III. (Dr. V. P. Gibney.)—S. F., a girl of nine years, was attacked in the left ankle some time in 1866. Her family history was not positively, but probably, bad; for syphilis was suspected in both father and mother; a sister died at three years, of "water on the brain," and a brother at a younger age, of some unknown cause. She herself had occasional attacks of phlyctenular conjunctivitis. The disease, however, was laid to a sprain, but the precise point at which it commenced could not be located by the child when first seen (Oct. 12, 1871). Five years after the outbreak of the disease she was wholly unable to walk. There was good mobility and but little tenderness. Marked atrophy of the limb was shown by the calf measurements: right, 8; left, 8. Ankle measurements were not given. The treatment, prior to the time she came under the care of Dr. G., had been by poultices; subsequently it was the expectant. During the year 1868 a sinus formed, leading to carious bone. It closed within twelve months. When treatment was suspended (Dec. 2, 1872) there was slight shortening of the limb; the left (diseased) ankle was a little smaller than the right, and correspondingly the foot somewhat shorter (one-quarter inch). The patient was then described as a stout, robust-looking girl, walking with perfect ease and without any limp, but showing unsteadiness in her gait. There was fair motion at the joint, which exhibited neither pain nor tenderness on rough handling.

Case IV. (Dr. V. P. Gibney.)—M. A. D., a girl of the laboring class, ten years old, and living in a malarial district, was dropped from her nurse's arms, and soon after her ankle was found to be swollen and painful. This was in 1867. Her family history was tuberculous upon the father's and mother's side. In September of 1870 she had another fall and a recurrence of the symptoms in the ankle. On July 14, 1871, the joint was examined and found movable over about one-half the normal arc. The tendo-Achillis was a little shortened, and she could not walk without crutches. Abscesses had formed on the outer side of the foot, and were discharging. The right calf measured 6¼ inches; the left 8⅜; the circumference about the right malleolus and the leg above it were much increased by new deposits of bone; right foot one-half inch shorter than the left. On April 30, 1873, the patient was discharged cured. She was then said to be "the picture of health," standing squarely on both feet and walking without a limp. The treatment consisted in leeching, the application of adhesive strapping, blistering, poultices, and liniments. The purely expectant plan was only carried out during the latter part of the treatment.

Case V. (Dr. V. P. Gibney.)—J. C——, a girl fifteen years of age, fell from a wagon in July, 1870, and several weeks afterward complained of pain and swelling in the left ankle. She was then suffering from chronic catarrh of the middle ear, a sequel to measles, which she had had four years previously. On October 24, 1871, abscesses formed and discharged until some time in the year 1875, but what bone or bones were involved was never known. The treatment was expectant, and the patient left the hospital, cured, on May 1, 1873. She was then robust and in good health, walking upon the sole of the foot, though it was slightly everted. The motion was limited, but the ankle bones were not enlarged and there was no tenderness. Flexion could be carried to 90° and extension to one-half the normal. In- and eversion one-half the normal. At one time there was a little talipes equinus, but it disappeared under treatment. At a subsequent examination (December 6, 1879) there was found to be no lameness, and the patient had been able to dance for some years past, but she was unable to skate well, as the joint was not very mobile.

Case VI. (Dr. V. P. Gibney.)—A. A——, a boy nine years of age, fell a victim to the disease in the autumn of 1870. No reason could be given for it, and the family history, so far as was known, did not lead to any suspicion of inherited blood disease. Nor did the boy, during his sickness, show any cachexia. For about one year the usual symptoms of chronic joint disease were exhibited. Finally, abscesses formed and pus was liberated, the discharge continuing about six months, during which "time seven or eight pieces of bone" came away. The expectant plan was resolutely adhered to, and the patient was discharged, cured, April 30, 1873. He then stood squarely on both feet, but walked with a slight limp. Toes were a little everted and ankle a little stiff. Malleoli were somewhat enlarged. At the final examination, before the report was made (December 4, 1879), the patient was working in a barber's shop, and though actively engaged upon his feet suffered no pain. The usual atrophy of the affected limb was found (circumference of right calf, 10¾ inches; of left, 11¾ inches). Right malleoli was still enlarged. No difference in length between the limbs, but the right foot was one-half inch shorter than the left. Flexion was carried a little beyond 90°. In- and eversion almost complete. Some tenderness over the joint on firm pressure, but no lameness. General health good.

Case VII. (Dr. V. P. Gibney.)—E. N——, a little girl, 4½ years of age, was attacked while convalescing from cholera infantum. She then had chronic enlargement and suppuration of some submaxillary glands, associated with chronic suppurative otitis of the same side, with recurring attacks of naso-facial erysipelas. The first indications of the ailment were in March, 1872. Her right ankle then became swollen and painful. On August 29, 1873, an opening formed leading to carious bone. It closed finally in five months. Some two years later she walked easily and with a very little halt.

Case VIII. (Dr. V. P. Gibney.)—A little girl, six years of age, after an attack of whooping-cough, had pneumonia, which nearly proved fatal. Soon after, chronic inflammation appeared in the right joint. This was in 1874. A grandmother had died of phthisis, otherwise the family history was good. It seems as if, in this case, the disease appeared first in the bone (the internal malleolus), and it is thought that the joint was never affected. The abscess formed four or five months after the first onset, and the discharge lasted about one year.

The result was a success under the expectant treatment, but there was atrophy of the entire right limb, with shortening of the foot to the extent of one-half inch.

Case IX. (Dr. V. P. Gibney.)—A boy, thirteen years old, was said to have sprained his right ankle in the spring of 1872. At any rate, symptoms of pain and swelling soon developed when he walked. After a while they abated, but recurred again. Finally joint disease became established, and an abscess broke on March 1, 1874. Several sinuses remained, and the parts about were thickened and infiltrated. There was also some anchylosis and muscular spasm. Pus discharged for eight months at the anterior part of the ankle-joint. The internal malleolus was thought to be chiefly involved. On April 1, 1875, he was regarded as cured, though, on subsequent examination, September 12, 1879, there was a little pain in flexing the foot. Still, the boy was actively employed as a clerk in a hardware store, and there were no outward appearances of disease. His health was also good, and he walked without lameness.

Case X. (Dr. V. P. Gibney.)—A boy, thirteen years of age, after an attack of measles, jumped from a height upon some solid object. A few weeks later sharp pain developed in the bottom of his heel, and he became lame. His family seemed to have been remarkably free from blood disorders, though a sister died of consumption. The patient, now a man thirty-two years of age, was treated by Mr. Colles, of Dublin. An abscess formed early, was incised and constitutional measures adopted. The abscess discharged for fourteen months. A cicatrix over the os calcis would indicate that this bone was certainly affected. Ankle measurements, made December 1, 1879, were as follows: right, 10, 12¾, 10; left, 10, 12¾, 10—absolutely no shortening. The patient never had a relapse. Pott's disease supervened after some interval, but, under Mr. Colles's direction, he was kept in the recumbent position for fifteen months, making an excellent recovery.

Case XI. (Dr. V. P. Gibney.)—A little girl, four years of age, of the laboring class, was attacked with disease of the left ankle in February, 1874. She was seen a year afterward, and then the whole foot and lower fourth of the leg were swollen. Pus discharged profusely from March 18, 1875, to September 13th of the same year, when she died of exhaustive suppuration, or septicæmia. The ulceration was very extensive, and nearly all the tarsal bones were involved. The treatment was expectant during the last six months.

Case XII. (Drs. V. P. Gibney and E. Peugnet.)—A girl, twelve years old, living at Fordham, found herself unable to walk in April, 1878, both ankles being swollen and painful. The child was cachectic, after an attack of scarlatina, and did not remember to have hurt the ankles. Family history decidedly good. The symptoms at first were much like those of articular rheumatism; then suppuration set in, and incisions were made into both ankles. Finally Dr. Peugnet removed bone from both feet at a number of operations. The openings closed in four or five months. At the final examination the patient was found free from lameness. Comparative measurements were naturally useless in this case.

Case XIII. (Dr. V. P. Gibney.)—A boy, thirteen years of age, whose parents were deaf-mutes, came under treatment in April, 1874. Small portions of bone came away from the foot in the neighborhood of the os calcis, which was the bone chiefly, if not the only one, diseased. The sinuses remained opened for fully three years and probably somewhat longer. In January of 1878 a cure seemed to have been effected, and indeed remained permanent. In March, 1879, examination of the parts showed that the shape and function of the foot was retained in every respect. Three cicatrices attested the existence of sinuses at an earlier date. The treatment was expectant. The calf was slightly atrophied. This is the second case thus far recorded where the result, so far as the ankle is concerned, was perfect. Yet it is barely possible that the other tarsal bones and those of the leg were not involved.

Case XIV. (Dr. V. P. Gibney.)—A little girl, five years of age, whose mother was tuberculous, and who herself had chronic middle ear catarrh, fell sick with trouble in her left ankle-joint. Abscess followed and a purulent discharge, which lasted, with an interval of one year, for twenty months. She was finally discharged cured in August, 1877, and has not been seen since.

Case XV. (Dr. J. L. Little.)—E. W., a boy, twelve years old. The first symptoms developed in February, 1877, and the disease is described as an acute necrosis. The child was placed under ether, and as the bone was loose, it was removed with the dressing-forceps. The astragalus and cuboid were roughened. The opening closed in about two months. Dr. L. was called in to decide whether amputation should be performed or not. He observes that he has seen at least one instance in which the foot might have been saved, if the nature of the disease had been properly understood. In three similar cases Dr. Little has been able to effect a cure without resorting to amputation.

Case XVI. (Dr. V. P. Gibney.)—A little girl, seven and a half years old, was attacked, in March, 1873, with inflammation at the left ankle, the pain intermitting by day. Phthisis was said to exist in remote branches of the family, but the special cause was thought to be a sprain. Abscesses formed and discharged between the dates of January, 1873, and May, 1878. Treatment expectant. On examination, December 3, 1879, it was seen that there was a little halt in the gait, but she complained of no pain in the ankle, except after running fast. Flexion and extension at the tibio-tarsal joint perfect. No pain or tenderness on handling. The following measurements were taken. Circumference: of right calf, 8¼ inches; of left, 7¾; of right ankle, 6¼; of left, 5¾; of right heel and instep, 7¾; of left 7¾; of right instep, 5¾; of left, 6; right foot one-half inch longer than left.

Case XVII. (Dr. V. P. Gibney.)—A boy, eight years old, after a fall, found that his left foot "dragged" in walking, but there was little pain or swelling.

The father was phthisical, and the child had whooping-cough and chicken-pox at the commencement of the disease. After the abscess was formed matter was discharged for five or six months. When all active symptoms had abated, a very slight valgus remained. Measurements, September 26, 1879: right ankle, 6½, 8¼, 6⅓ inches; left, 5½, 7¾, 5⅞; right calf, 8 inches; left, 7⅓; right foot, 7 inches; left, 6½.

Case XVIII. (Dr. T. E. Satterthwaite.)—In April of 1875, a girl, six years of age, adopted from a foundling institution, complained of pain in the right ankle. Her foster parents found it swollen and red. As they exercised unusual watchfulness over the child, a traumatic cause was excluded, and they were inclined to attribute it to the manifestation of blood disease, especially as suspicious eruptions and enlarged lymphatic glands were observed in early life. When the child was first seen the malleoli were enlarged, the parts about the ankle were infiltrated, "pulpy," hot, and constantly throbbing. Under extension by Buck's apparatus, applied to the foot only, these unfavorable symptoms were relieved in two weeks, and the child was allowed to go about with Sayre's extension brace, which gave great comfort. This treatment was only suspended once, and for a few weeks. During this time, as a sequel to violent and prolonged hand-rubbing, an abscess formed and soon broke. The discharge continued one year, and then stopped permanently, leaving a small cicatrix. The child was soon able to give up the brace, and last winter danced and skated without showing any symptoms of her former trouble. The limb was not shortened, so far as measurements can be relied on, but the calf was atrophied (right, 7⅛ inches; left, 8¾). Extension at the tibio-tarsal joint was much limited and flexion was abolished, but the foot turned neither inward nor outward. The child had the appearance of excellent health. Some time during the present year she died of a sudden and unknown attack while in Toronto, Canada.

Case XIX. (Dr. T. E. Satterthwaite.)—A boy fourteen years old, living in Williamsburg, sprained his foot while going to the water-closet. Liniments were applied, and after a week's rest he thought no more about it. After an interval, pain set in and the symptoms of chronic ankle disease became established. The boy was not strong physically, and the family was phthisical. After adopting various methods of treatment, including leeching, hot and cold applications, rubbing, and strapping, an abscess formed at the end of six months and broke. General disorganization of the tarsal bones seems to have ensued, and amputation was regarded as imperative by a hospital surgeon. Consent would not be given. With the hopes of saving the foot, a conservative operation was planned and carried out December 20, 1876. After ether had been given, vertical incisions were made over each malleolus, and the astragalus, scaphoid, cuboid and os calcis, in part, were removed periosteally (Dr. Satterthwaite). As the bones were quite soft they were simply scooped out with the chisel (gouging). The foot, which previous to the operation was extended so far as to form an angle of 135° with the leg, was carried to a right angle without section of the tendo Achillis. The limb was thereby shortened about 1⅓ inch. Through the wounds an oakum rope was passed, and then a fenestrated plaster splint applied. This was not removed for six weeks. At the time of the operation the case seemed almost hopeless, as there were six sinuses leading to dead bone, one on the shaft of the tibia, two inches above the ankle-joint. The boy also had night-sweats. After the plaster-of-Paris splint was removed, Sayre's ankle-extension brace was substituted. On October 1st, the same year, he was walking without crutches, his night-sweats had stopped, and his health had improved. About January 1, 1878, the patient went to work, and continued in active employment until his death. The case was regarded as a cure, as he rarely used a stick, and walked about without lameness and made no complaint. A single sinus had not healed. It was covered with a dry scab, but on removing it there was a serous oozing. The patient died of some unknown disease in 1879, after a few days' illness.

Case XX. (Dr. Reid.) [Communicated by Mr. J. C. Phillips, student of medicine.]—M. K., a little girl, four years of age, is said to have met with an injury during her first year, though the history is obscure. There was no constitutional taint and the family history was good. According to the mother the disease originated in the "sinews." After suppuration had been established incisions were made. The suppuration lasted more than two years. The suppuration has now stopped, and the cure is complete. The child is in the country.

Case XXI. (Dr. Kenneth Reid.) [Communicated by Mr. J. C. Phillips.]—"John," a boy, two years of age, of a strumous diathesis, was attacked with chronic joint disease, which was located first in the bone. There was great swelling and infiltration extending up the lower third of the leg. An operation was performed by Drs. O'Dwyer and Reid, by which the carious bone was chiselled out, and an oakum seton, saturated in carbolized water, introduced through the joint. This was renewed from time to time. The result was a cure, and the child is now well and hearty.

Case XXII. (Dr. T. E. Satterthwaite.)—In August, 1878, the mother noticed that her little boy, twenty-two months old, walked "crooked," and that she could not button his shoe. Traumatism and blood infection could be excluded so far as the history went. Soon the child had "starting pains" in the night, but no suppuration occurred at any time. The treatment, at first, was hot water several times a day; then rest; then at the time he first came under observation a plaster-of-Paris splint was applied for five months.

There was considerable infiltration under the internal malleolus. The child passed from observation in February, 1879.

Case XXIII. (Dr. T. E. Satterthwaite.)—M. C. K., a boy, four and a half years old, whose condition indicated great poverty, was brought to the Demilt Dispensary with chronic ankle disease and a sinus leading to dead bone behind the external malleolus. A vertical incision was made over either malleolus, some bone removed (astragalus), and a rope of oakum was passed through the incisions. It was then retained *in situ* one month. The child was also given cod-liver oil, and he soon began to walk on the foot without pain, and his general condition improved, but at this time Pott's disease manifested itself, and the child was lost sight of.

Case XXIV. (Dr. E. H. Bradford, Boston, Mass.)—A boy, three and a half years of age, began to exhibit symptoms of disease in his right ankle in November, 1877. The site of the commencement of the diseased process, whether in the bone or adjacent soft parts, was not determined. Dr. B. did not see him until March, 1878, when it was found that the whole dorsum of the foot below the malleoli was infiltrated. The treatment adopted was, in brief, the application of a stiff bandage; then rest for several months; later, incision and gouging, and finally, removal, by dissection, of the astragalus and scaphoid. In the winter preceding Dr. B.'s first examination (1877), an opening had formed in the soft parts leading to the carious bone. After the operation just described the discharge lasted six months, when the sinus closed permanently. Caries had involved the end of the tibia, slightly roughening it. At the final examination in June, 1879, the foot was found shortened three-fourths of an inch; the limb was of normal length. Calf, ankle, and instep were not measured, but there was no noticeable change as compared with the other limb. Flexion and extension of the joint, each 15°. So far as talipes was concerned, none resulted, and there was no pain or tenderness; in fact, a permanent cure seemed to have been effected.

The expectant method was tried a year without benefit; gouging also seemed to produce no favorable result, and for three months the symptoms were worse rather than better. The final operation is described as follows: "A straight incision was made on the dorsum of the foot, and a second curved one on the outside of the foot, below the malleolus, down to the astragalus, which was carious throughout (a portion has, as before stated, been removed by gouging); this was removed by dissection, and afterward the scaphoid, which was found to be partially carious; the lower end of the tibia at its anterior edge was bare of cartilage to a slight extent; this was simply curetted. The operation and subsequent adjustment of the parts were done antiseptically, but as the dressings became foul in a week the open method was subsequently employed. After this operation the boy's condition, which previously had been poor, improved and continued excellent.

CASE XXV. (Dr. Cammann, reporter.)—A boy, seventeen years of age, was admitted into hospital, New York city, with disease in the right ankle. The first symptoms dated from October 13, 1878. No injury was thought to have produced it, and the bone seemed to be first affected. On examination by Dr. C., January 1, 1879, the following story was elicited from the patient: On October 26, 1878, the whole foot had become swollen, red, and hot, chiefly on the outer aspect. A few days after the symptoms became marked, incisions were made, but only blood was liberated; a few days later again other incisions were made, and a large quantity of pus was evacuated; poultices were then applied. Still later, other incisions were made. Amputation through the epiphyses of tibia and fibula was performed three weeks and four days after the onset of the symptoms. The extent of disease, as determined by subsequent examination, was very great, involving the following bones: Articular surfaces of tibia and fibula, astragalus, os calcis, scaphoid, cuboid, internal, middle, and external cuneiforms; articular surfaces between second and third and fourth and fifth metatarsal bones. The shafts of metatarsal bones and phalanges were not involved. At last accounts the wound was not entirely healed, two small ulcers still existing in the stump, and there was some tenderness.

CASE XXVI. (Dr. Cammann, reporter.)—A girl, aged fourteen, was admitted into hospital in the middle of February, 1879, with disease of the right ankle. On May 9, 1879, the foot is described as being swollen and painful. Poultices were then applied and maintained for about two weeks, when the cuboid, external and middle cuneiform bones were removed. As the case did not progress favorably, amputation was performed October 14, 1879. It was then found that the tarsus and metatarsus had become involved, the phalanges being the only bones of the foot not affected. The cure was permanent.

HYPOSPADIAS.

CURE BY A SINGLE OPERATION.

By F. N. OTIS, M.D.,

CLINICAL PROFESSOR OF GENITO-URINARY DISEASES AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

J. W——, aged thirty-four years, came under my observation June 10, 1876, with the following history: Some two years previous he had a suspicious sexual contact, which was soon followed by a purulent discharge from the meatus urinarius. Within a few days, evidences of chancroidal ulceration presented at the urethral orifice. The orifice was so small that it not only prevented any local applications to the ulceration within the urethra, but interfered seriously with micturition. Extension of the ulcerative action ensued. This soon assumed a phagedenic character, and carried away the corpus spongiosum and integument of the penis from a point just at the base of the glans nearly an inch backward. The surface of ulceration finally healing, a fistulous opening about one-half an inch in extent was left, through which all the urine was passed. The condition of the penis when presenting, June 10, 1876, is shown at Fig. 1, made from a sketch taken at that time. The surface adjacent to the fistulous opening was covered with mucous membrane fully three-fourths of an inch in breadth posteriorly, narrowing to about one-third of an inch at the base of the glans.

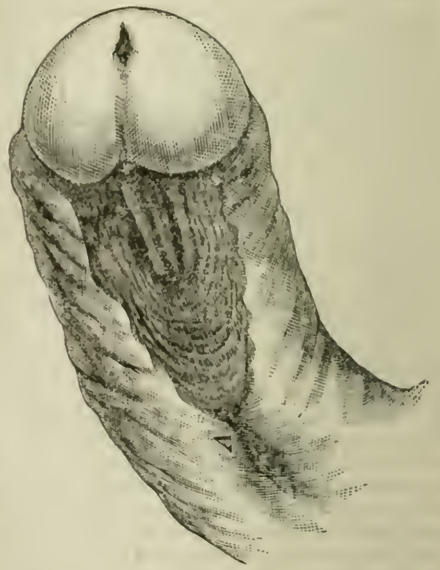

FIG. 1.

Circumference of the penis 3¼ inches; meatus urinarius, 16-f. Urethra, as measured by the urethrometer, full size from bulb to the posterior border of the fistula (viz., 32-f.). At this point a hardened ring of tissue presented, which, after a little steady pressure, allowed the passage of 30-f. Meatus divided to 30-f.

Seven days after (June 17th), the wound of meatus having healed, patient was placed under the influence of ether. Present and assisting, my associate, Dr. L. B. Bangs, and Dr. M. J. De Rosset, of New York.

The inferior border of the glans was painted thickly with white paint up to the line marked 1, 2, in diagram, Fig. 2. The loose integument of the penis was then drawn forward until the fistulous opening was completely covered, and the mucous surface surrounding the fistula was brought into easy apposition with the line 1, 2, at base of glans. The tissues were then allowed to resume their former position when the paint line at 1, 2, was found to have been repeated at 3, 4. This afforded an exact guide as to the amount of tissue required to be brought forward to reach easily to the line 1, 2, at the base of the glans. Integument and mucous membrane was then carefully dissected off, for the space indicated by the paint line, leaving only the flaps of mucous membrane at 5, of a size and shape sufficient, and suitable to cover the fistulous opening, and to serve as the new floor of the urethra at that point. A short straight silver tube, No. 30, was then introduced through the meatus and well into the urethra beyond the fistula. Two deep sutures were then introduced at the points in the diagrams marked +. The freshly dissected surface was then brought forward into apposition with the line 1, 2, at the base of the glans, and the two deep sutures carried through the integument at the point overlying their insertion in the tissues of the corpus spongiosum, thus securing the complete coaptation of the longitudinal portion of the flap. The posterior and transverse portion was then firmly attached to the tissue at the base of the glans 1, 2, by deep interrupted sutures of fine silk thread about one-sixth of an inch apart.

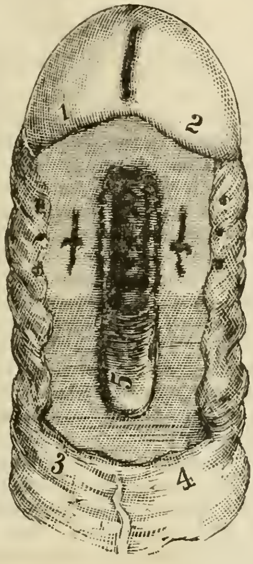

Fig. 2.

A small, soft (Mercier) catheter was then introduced through the tube and into the bladder and retained. As there was some tendency to paraphymosis, I divided the constricting preputial integument freely. Light pasteboard splints covered with borated cotton were then applied to the superior and inferior surface of the penis and retained by a bandage. The cold-water coil was then applied, and a suppository of morph., one-fourth of a grain, was then administered.

Tube and catheter retained without trouble. No urine escaped except through the catheter, and but slight swelling of the parts, up to the night of the 22d, three days subsequent to the operation. Erections then began to be troublesome. Neither the cold-water coil, application of ice, nor bromide of pot. in thirty-grain doses, proved sufficient to prevent them entirely. The preputial swelling thus induced caused partial paraphymosis in spite of the previous measures taken to prevent this accident. The œdematous tissue was tapped with a hypodermic syringe, and the tension much relieved.

Stitches taken out on the morning of the fifth day. Swelling had subsided to some extent, and wound was found in fair condition. Parts were kept clean with carbolic lotion, and continued apposition and support secured by the pasteboard splints. Tube and catheter removed; no trouble from either at any time. Urine now to be drawn off as required, patient himself passing the catheter. Matters went on in this way for the following six days, making eleven days in all since the operation. No urine had passed through the wound. Examination showed that only partial adhesion by first intention had taken place. The parts were kept in perfect apposition by the splints. The swelling was almost entirely gone. Patient walked about now without discomfort. Tube 30-f. was introduced into the urethra and well beyond the point of operation daily. Purulent urethral discharge quite profuse, but the parts were painless. Patient allowed to go home to a distant State, with instructions to continue use of catheter and the support of the splints for at least two weeks longer, before passing his urine *per viam naturalem*, and to keep up the support of the splints for a week or two longer still. The patient was not seen or heard from until the 18th of the following December, six months from the date of operation, when he reported in person, having carried out all directions with fidelity, with results apparently satisfactory. The above sketch (Fig. 3) represents the appearance of the restored penis.

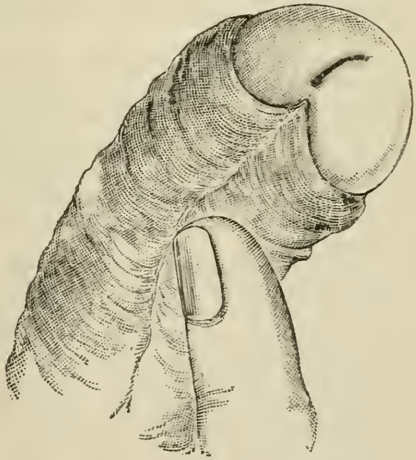

Fig. 3.

Union at every point had been complete. There was a slight muco-purulent urethral discharge. Patient very desirous of marrying and anxious to get rid of the discharge. Injections and internal remedies had been used for this purpose for some months without effect.

Examination of the urethra by means of bulbous sound revealed a strictured point just behind the site of the orifice of the former hypospadias, one and a half inch from the meatus urinarius.

This stricture was found to be very resilient, distinctly defined by 26-f. bulb, but permitting the passage of 30-f. sound without much pressure, and was then divided with the dilating urethrotome up to 34-f. Subsequently to this operation, No. 32-f. bulbous sound was passed through the entire pendulous urethra with ease. No subsequent trouble from bleeding or other causes. A solid steel sound was introduced beyond the site of operation every second day, until the eleventh day after the division of the stricture. At this time, the wound in the urethra having healed and the urethral discharge having entirely disappeared, the patient left for his home, apparently well in every respect. June 20th, 1879, over three years subsequent to the operation on the hypospadias, I learned that he had married, and that the cure, both of the stricture and of the hypospadias, as far as he was able to judge, had been complete and permanent.

108 West Thirty-fourth Street, July 7, 1880.

A CASE OF ABSCESS OF THE SPLEEN.

By GEORGE H. STONE, M.D.,

ACTING ASSISTANT SURGEON, MARINE HOSPITAL SERVICE, SAVANNAH, GA.

Frank Taylor, a native of Savannah, Georgia ; aged 32 years ; married. Has been employed for several years on the tug-boats running on the Savannah River. Residing during that time on Hutchinson's Island, opposite the city. The surface of that island consists of reclaimed rice fields, and up to 1877 was overflowed at every tide. The island is one upon which no white person could live with impunity before it was drained, and very few choose to risk it now.

From September 12 to September 19, 1878, I treated the patient for remittent fever and diarrhœa. From April 11 to April 16, 1879, he was again under treatment for eczema cruris. July 2, 1879, I was called to see him, and found him suffering from remittent fever and splenitis. Acute splenitis developed, and on August 4, 1879, his condition not having improved, he was admitted to St. Joseph's Infirmary Hospital.

On admission his temperature was 104°, pulse 120 ; the fever remitting in the evening. In a few days the acute febrile condition subsided, leaving behind pain over the spleen. Percussion developed immense enlargement of the spleen to the median line in front, downward almost to pelvis. General debility, with hectic flushes every day. The general prostration gradually increased until about September 10, when I detected fluctuation. On the 14th day of September, 1879, I introduced an aspirator needle, and drew away 1,000 c.c. of pus, after which the tumor subsided to half its former size. The aspiration was repeated on the 21st and 29th with a like result.

On the 10th of October, after inducing anæsthesia with chloroform, I made an incision just above the crest of the ilium, where the pus seemed to point, and evacuated 250 c.c of pus. The abscess continued to discharge until his death, November 14, 1879. At the post-mortem examination (which was only partial on account of decided opposition of his friends) the abdomen was opened, and the viscera were found healthy, with the exception of the spleen, which organ had been entirely absorbed, except the capsule which formed the sac of the abscess and enclosed the pus.

A fistulous opening existed, leading downward and outward, between the quadratus lumborum and transversalis muscles, having its exit about half way between the crest of the ilium and floating ribs.

There was a capricious appetite throughout the disease, with a constant tendency to find fault both as to quantity and quality of the food furnished.

Reports of Hospitals.

NEW YORK HOSPITAL, N. Y.

NINE CASES OF SUNSTROKE.

Service of Dr. C. E. Hackley.

(Reported by F. M. Townsend, M.D., House Physician.)

It is well known that exposure to the direct rays of the sun is not always necessary to produce sunstroke, for cases arise from merely overheating the body in close, badly ventilated apartments, in prisons, barracks, etc., and occur sometimes by night as well as by day. Those arising from exposure to either solar or artificial heat, as a rule, show the following train of symptoms : coma, with contracted pupils and suffused conjunctivæ ; a hot, dry skin ; a rapid but full pulse, and a very high temperature. Not infrequently tonico-clonic convulsions are present.

There is, however, another variety, better termed heat-prostration, which is shown by syncope, or even collapse, a cold, damp skin, a rapid, thready pulse, cold extremities, and only a slight elevation of temperature.

In many cases premonitory symptoms show themselves, such as a dull, aching headache, or a feeling of fulness and distention in the head, dizziness, and extreme weakness. The following cases were of the former variety ; one case only of the latter kind came under observation, and unfortunately no notes were taken of it.

In the treatment, both the cold bath and the wet pack were used. The bath was begun with water at 75 F., and slowly reduced to 65° F. In using the wet pack the patient was wrapped in a wet sheet at the temperature of 65° F., and placed on a fever-cot, the sheet being sponged with water every five to ten minutes, according to the amount of fever.

It was noticed that a tendency to failure of the heart and œdema of the lungs occurred in those cases where a rapid fall of temperature occurred *during* the bath ; that convulsions occurred more frequently *after* the bath ; and that a second and rapid rise of temperature in these cases was the rule.

Case I.—May 27th, William M., æt. 45, Ireland, hostler. This patient, while working in the sun, became overheated and drank freely of ice-water. At 10 a.m. he staggered and fell, and was brought to the hospital a few minutes later in an unconscious state, breathing stertorously with a loud mucous rattling in the trachea. Both conjunctivæ were injected, the pupils finely contracted, and the skin intensely hot ; pulse, 158, full and strong ; respiration, 30 ; temperature, 110°.*

The patient was put in a bath, and an ice-cap placed on the head. Two hours later the thermometer registered 103.5°, and the patient was removed to the fever-cot, wrapped in a wet sheet, and given ℥ ij. brandy per rectum. The patient, still unconscious, moaning loudly and grinding the teeth, soon began to suffer severe clonic spasms of both arms. The temperature continued to fall, and at 12.40 P.M. was 102°. The pack was then discontinued and stimulants given.

---

* All temperatures were taken in the rectum by one of the house staff, and two, and sometimes three, thermometers were used in the same case.

At 4 P.M., the temperature having risen to 104°, the pack was reapplied for a short time, resulting in a fall to 101° within thirty minutes, and the patient seemed much better. This was temporary, however, for the temperature rose again; the heart, previously strong, began to fail, and œdema of both lungs occurred. Finally, at 7 P.M., he died; temperature, 104.2°.

CASE II.—This patient, during the first few days of her illness, was under observation at Chambers Street Hospital. The previous history and treatment were furnished me through the kindness of the house surgeon, Dr. Moore.

May 27th, Mary McQ., æt. 35, Ireland, bookbinder. This patient was poorly nourished, and had suffered more or less for years with subacute rheumatism. She worked in a close apartment in a bookbinding establishment, and for two days previous to her present illness had complained of severe headache, nausea, and weakness. To-day, while working, she was seized with precordial distress and faintness, and was obliged to quit work. One-half an hour later, after vomiting freely, she fell unconscious, and, when removed to the hospital at 4.10 P.M., was fully comatose, having automatic movements of the left arm and grinding of the teeth. Both conjunctivæ were suffused; the pupils finely contracted and insensitive to light; pulse, 146; respiration, 38; temperature, 109°. The breathing was labored and noisy, and each inspiration was accompanied by a sinking in of the intercostal and supraclavicular spaces.

The patient was placed on a cot, rubbed with ice, and had an ice-bag applied along the spine. Thirty minutes later the wet pack was used, and two cold-water injections were given, which thoroughly emptied the bowels of a large quantity of foul fæcal material. The temperature steadily fell, reaching 104° F. at 10 P.M. The pack was discontinued, and the patient then sprinkled with water by means of an ordinary watering-pot, and given stimulants. The automatic movements had ceased, but clonic spasms of unusual severity affected the whole left side and continued during the night.

The next morning the general condition was much better, though coma still remained. The spasms had ceased, the breathing had become less labored, the pulse stronger, and the thermometer registered only 101°.

Until the evening of May 30th, just three days after admission to the hospital, this patient remained in an unconscious state. She had, during this period, continual fever, not above 101–2°, and great restlessness, and was nourished almost entirely by nutritive enemata.

On regaining consciousness her only complaint was extreme weakness, and almost one week elapsed before she was allowed to sit up. The only other circumstance worthy of note occurred on June 5th, when a desquamation of the cuticle over the entire body began, resembling greatly the desquamation of scarlet fever. She has now entirely recovered and resumed work.

CASE III.—June 18th, John S., æt. 40, Ireland, laborer. To-day, while exposed to the sun, complained of feeling badly, and at 4 P.M. fell unconscious.

On admission the patient was comatose, suffering convulsive twitchings of the left side of the face and body. Both pupils were contracted and the conjunctivæ injected; pulse, 134; respiration, 24; temperature, 106.8°. The wet pack was applied for three hours, and the temperature fell to 100.7°. He was then well rubbed with dry towels, put in bed, and given ℥ ij. brandy per rectum. At 7.30 P.M. temperature 99.8°. As the temperature fell the spasms became less frequent, and finally disappeared. At 9 P.M. the patient was in a condition of stupor, and on attempting to rouse him, a severe tonic spasm occurred lasting three minutes, and while it lasted the limbs would stay in any position they were placed; the breathing became shallow, and the pulse lost at the wrist. Hyperæsthesia of the whole body remained for an hour after this convulsion, a touch anywhere, but especially in the folds of the neck, causing the patient to cower and shrink away with fright, while an unexpected tap threw him at once into a spasm.

At 10 P.M., after a general tremor which lasted ten minutes, consciousness returned, and the patient spoke a few words. Temperature now 102.5°, but fell to 100° in the morning. Improvement progressed favorably, and, excepting weakness, there was no complaint.

On June 25th he was discharged cured.

CASE IV.—June 25th, Michael C., æt. 56, Ireland, laborer. This patient, a strong, well-built man, while exposed to the sun, became weak suddenly and fell unconscious at 2.50 P.M. He was comatose and breathing rapidly; the face and whole body were cyanosed, the pupils contracted, and the conjunctivæ injected; pulse, 158; respiration, 40; temperature, 110° F. At 3.05 P.M. he was put in a bath, and within *fifty* minutes his temperature fell to 102.4°; the pulse ran up to 180 per minute, and was very feeble, and the extremities became cold. He was removed immediately, given brandy ʒ j. and digitaline $\frac{1}{24}$ grain hypodermically, wrapped in blankets, and put in bed. The pulse grew better almost immediately, and the cyanosis partly disappeared; but by 4.15 P.M. the temperature had gone down to 98.9°, and he became very restless. Slight twitchings of the facial muscles and grinding of the teeth were now noticed, and the patient groaned loudly. A short time afterward a general convulsion followed, during which the head was drawn forcibly backward, the jaws were clenched, and the extremities rigidly extended. This tonic state lasted about forty seconds, and, relaxing, gave place to clonic spasms so violent that the patient could scarcely be kept in bed. These convulsions followed each other in rapid succession, occurring every eight to ten minutes. They were effectually controlled by ether, and for the next two hours the patient was kept anæsthetized; for every attempt to remove the ether was followed by a renewal of the convulsions. At 6.30 P.M., pulse, 144; respiration, 30; temperature, 105.8°. The fever having risen so rapidly, the pack was applied and kept up until 10 P.M.; the thermometer then registered 101.8°. The convulsions had become less severe, the general condition improved, and the patient partly regained consciousness, answering questions rationally. This improvement, however, was only temporary, for at 1 A.M. of the 26th he became fully comatose again; the temperature rose to 103°, and he suffered the same tonico-clonic convulsions as before, making the giving of ether necessary until 6 A.M.

In the early part of the forenoon the convulsions ceased entirely, consciousness fully returned, and the temperature fell to 101.7°, and the pulse to eighty good pulsations per minute. The case now seemed a very hopeful one, but in the afternoon he again became comatose, and the temperature rose to 105° F. at 5 P.M.; the convulsions did not return. The patient was wrapped in wet sheets at 75° F., and left so all night. Finally, at 4 A.M. of the 27th, the temperature being reduced, he became conscious, and from that time he began to convalesce. During the next ten days he had to be fed, being unable to use his arms; and three weeks elapsed before he was allowed to sit up. After the acute stage of his illness he lost flesh very rapidly, and suffered severe headache and dizziness for more than three weeks.

On July 28th he tried to walk for the first time, but was obliged to confess himself still weak. At present he is gaining flesh and strength rapidly, and in a few weeks will be able to attend to work.

CASE V.—June 27th, William L., æt. 42, Germany, laborer. This patient had been drinking heavily all day, and at 5 P.M. was found in his room in an unconscious state. On admission he was comatose, had loud, stertorous breathing, contracted pupils, and hot skin; pulse, 144; respiration, 38; temperature, 108.6°. On putting the patient in the bath (temperature 75° F.), respiration suddenly ceased. He was removed immediately, and artificial breathing was resorted to, and in a few minutes he breathed regularly. In thirty minutes the temperature had fallen to 105°, but at 6.40 P.M., while in the bath, the heart failed, and in spite of stimulants, artificial respiration, etc., he died in a few minutes.

CASE VI.—June 28th, Peter K., æt. 22, laborer. This patient was brought to the hospital at 8.05 P.M. in a dying condition. He was unconscious, breathing stertorously, with a loud rattling in the trachea. The face and body were greatly cyanosed; profuse frothy mucus issued from the nose and mouth; the radial pulse was lost, the extremities cold, and the thermometer registered 108°. Examination of the chest revealed intense pulmonary congestion and œdema. The patient being unable to swallow, brandy and digitaline ($\frac{1}{48}$ grain doses) were administered hypodermically, and large cold-water injections were used instead of the bath. The heart did not respond, but the temperature fell to 105.8° at 8.50 P.M. Ten minutes later a clonic convulsion occurred, opisthotonos became marked, the contents of the bowels and stomach were ejected, and the patient died.

CASE VII.—June 30th, James G., æt. 40, Ireland, waiter; was obliged to remain nearly all day in a kitchen where the temperature ranged between 100° and 101°, and for two or three days previous to this attack he suffered headache, dizziness, and a sense of prostration. At 8.30 P.M., while working, he fell unconscious, and his temperature, taken immediately, showed 107° F. He was wrapped in a wet sheet, after being rubbed with ice for a few minutes, placed in the ambulance, and brought here at 8.50 P.M. He was still comatose, had contracted pupils and stertorous breathing. He was left wrapped up in the sheet and sponged frequently with cold water. At 9.30 P.M., pulse, 144; respiration, 30; temperature, 102.4°. He was then removed from the pack and placed in bed, and almost immediately began to suffer convulsive twitchings of the upper extremities. These rapidly grew severe and involved the whole body, and were accompanied by loud moaning and grinding of the teeth. Ether promptly checked them. At 10 P.M., pulse, 140; temperature, 98.4°. The convulsions now subsided, and the ether was stopped. At 10.35 P.M. a general tonic convulsion, lasting twenty seconds, occurred, and was followed by loud groaning and intense restlessness, the patient tossing violently from side to side. Shortly after, however, he grew partly conscious and spoke a few words. At 11.35 P.M., the temperature having risen to 104°, the pack was reapplied, and, after a slight rise of 0.6° at 12.30 A.M., the temperature steadily fell to 101.2° at 2.30 A.M., July 1st, and the patient was given potass. bromide 45 grains, which soon quieted the restlessness and induced sleep. He awoke a few hours later complaining of much weakness, but from this time went on to convalescence without a bad symptom, and on July 3d he was discharged cured.

CASE VIII.—July 12th, Edward J., æt. 30, single, porter. This patient, after working hard all the morning in the sun, walked a short distance complaining of dizziness, confusion of ideas, and weakness, and then fell unconscious. He was removed to the hospital at 2.30 P.M., comatose, and suffering clonic spasms of the whole body. The face was pale, the eyes suffused, and the pupils contracted; pulse, 140; respiration, 38; temperature, 108.2°.

He was put in a bath and kept there nearly two hours, when the temperature showed 101°. The patient was then rubbed well and put to bed, and within one-half hour the spasms ceased, and he became fully conscious. He recovered rapidly, and, excepting a rise of fever to 101° on the second day, nothing happened until July 16th, when a desquamation of the cuticle appeared over the abdomen and chest, resembling that seen in Case II. July 20th he was discharged cured.

CASE IX.—July 14th, Cornelius R., æt. 45, carpenter; was brought by ambulance, at 5 P.M., in an unconscious state. He was seen to fall at the corner of Pearl and Dover Streets about 3 P.M., but beyond this there was no previous history. On admission he was found comatose and breathing stertorously. The skin was intensely hot, and the pulse rapid; respiration, 35; temperature, 109°.

He was put in the bath with an ice-cap to the head, and given brandy, ʒ j., hypodermically, to stimulate the heart. While in the bath the patient showed signs of œdema of the lungs, and he was removed, placed on a bed, and given stimulants freely. The temperature, which had fallen to 108°, rose to 110.2°, and the pack was immediately applied. The œdema lessened, and the pulse improved after giving digitaline, $\frac{1}{24}$ grain, hypodermically. At 6 P.M. temperature had fallen to 102.2°, and the pack was stopped.

At 7 P.M. patient was still comatose, breathing loudly, and had tonic rigidity of both arms and the muscles of the neck, the latter drawing the head far back. The temperature fell to 98.4° at 7.30 P.M., and the pulse became lost and the patient sank into a condition of collapse. Hot bottles were applied to the body, and stimulants freely given, but at 9.15 P.M. he died, the temperature being 103.4°.

◆

NASHVILLE MEDICAL COLLEGE.—Dr. W. K. Bowling has been made Adjunct Professor of the Theory and Practice of Medicine in this college. Prof. Thos. O. Summers, late of Vanderbilt and Nashville Universities, will occupy the Chair of Physiology. Dr. J. B. Lindsley has taken the Chair of State Prevention Medicine.

Progress of Medical Science.

Chloral Hydrate in Acute Gastro-Enteritis of Children.—Prof. Kjellberg asserts that there is no medicine equal to chloral for checking the vomiting in the acute gastro enteritis of children. Being rapidly absorbed, it calms the patient, stops the vomiting, and often checks the diarrhœa. It is best given by enema, so as not to risk its rejection by the irritable stomach, and it should be given soon after a passage. The dose for a child of from five to six months is from 3½ to 4½ grains, while to a child of from twelve to fifteen months, from 7½ to 9 grains may be given. The bulk of the injection should not exceed a dessertspoonful. The enema may be repeated two or three times daily, and the dose may be increased, if it is found necessary. To increase the effect of the chloral, Prof. Kjellberg generally adds to each enema a drop of tinc. opii, and if stimulants be indicated, five to fifteen drops of liq. Hoffman. At the same time the other ordinary remedies are not neglected.—*The American Practitioner*, June, 1880.

The Surgical Treatment of Epistaxis.—Dr. Thurston writes that he has found the injection of cold water by means of a Higginson's syringe very serviceable in the treatment of this symptom. The water is injected into the nostril not bleeding, and allowed to flow out of the other nostril. This drives out the clots and often arrests the bleeding at once; if it should not, he injects a weak solution of perchloride of iron, which is generally successful. A jet of water thrown up in the same way is most useful in dislodging foreign bodies from the nostril.—*British Medical Journal*, June 5, 1880.

Monthly Sanguineous Discharge in an Infant.—Mr. Harle, of Enfield, reports this case: The patient was the youngest of three children, girls. At the age of five months the mother observed a bloody discharge, which continued about three days, and returned every month till the patient was nine months old. At the age of ten months she was weaned, and the discharge did not return that month. It reappeared at the eleventh month, and then periodically until she was fourteen months old, when she died of diarrhœa. At the autopsy, there were marks of blood, somewhat dry, on the pudendum, labia, and peritoneum, corroborating the mother's statement that the child had recently had "the monthly discharge." The pudendum was large, and covered with fine hair. The vagina was healthy. The uterus was large; when removed, it measured an inch and five-eighths in length externally. The os was very patent; the lips congested. There was nothing abnormal in the cavity. The vessels of the broad ligament were injected. The left ovary was twice as large as the right; it was dilated, forming a cyst of the size of a horse-bean. The right ovary contained a number of small cysts, each about the size of a pin's head.—*The British Medical Journal*, June 5.

Paralysis Spinalis Spastica.—At a clinical lecture held at the Glasgow Royal Infirmary, December 8, 1879, Dr. M. Charteris presented a typical case of *paralysis spinalis spastica* (Erb-Charcot), being the first true case which has been reported from the west of Scotland. Patient, female, æt. 36, the mother of ten children, had been enjoying good health until ten months previously, when she became pregnant with her tenth child. Her confinement was noticeable for the entire absence of a lochial discharge. She kept her bed for three weeks, and on rising found that she was unable to walk without crutches. Day by day she noticed that she had greater difficulty in putting her heel to the ground, and after a time she could only place her toes there. As she lay in bed, her thighs were flexed slightly upon the pelvis and the legs forcibly upon the thighs. The adductor muscles of the thigh were strongly contracted—so much so that the knees were locked forcibly together and could not be separated; the thighs and legs could not be extended to any great degree. Sensibility was not affected, and the muscles of the leg and thigh, though flabby, were not atrophied. The entire condition of the patient faithfully illustrated Erb's clinical picture of the disease known as *paralysis spinalis spastica*. The pathology of the disease involves the lateral columns of the spinal cord. According to Charcot and Erb, it consists in a chronic inflammatory process in the posterior divisions of the lateral columns, but as yet this theory has not been verified by a post-mortem. The treatment in this case produced very little change in the patient's condition. Every remedy which might be considered useful, constant current, etc., had been tried, but without effect. Under chloroform the limbs could not be extended any farther than without it. The patient was therefore discharged uncured.

Less than forty cases of this disease have been reported, and these with very unsatisfactory results as to treatment, but one case of recovery having been reported.

Hæmoglobinuria caused by the Inhalation of Arseniuretted Hydrogen.—Dr. Eitner, of Breslau, reports several cases of the above. A professor of physics, a tutor, and two students were suddenly attacked, after the experimental inhalation of what was supposed to be pure hydrogen gas. The professor gave the following history: On the first of November, in the afternoon, he suddenly experienced a general malaise, which forced him to take to his bed. He passed the night wretchedly, was "feverish," restless, harassed by one continually recurring dream, and experienced alternately hot and cold sensations. Toward morning he began to perspire freely. On looking at his urine, which had been copiously voided during the night, he was startled by its bloody appearance. In addition he now complained of a profound weakness, especially about the knees, general prostration, and the loss of appetite. He had been previously quite healthy, of a robust constitution, and was considered quite a pedestrian. Examination elicited the absence of fever, a feeble but regular pulse, coated tongue, icteric color about the forehead and breast, no pain, and bloody urine. The latter showed no deposit, and was free from albumen. On the following day, after a good night, the patient was again up and about, his urine being clear, of normal color, and still free from albumen. His appetite had also improved. On the next day, all the previous symptoms returned; the urine was then found to contain much albumen, was reddish brown, and did not show any red blood-globules. Hæmoglobinuria was therefore diagnosticated. The patient soon began to improve and finally completely recovered.

The other patients had similar symptoms, but with them the attacks were less severe. That the hæmoglobinuria resulted from intoxication with arseniuretted hydrogen was clearly shown by a subsequent chemical examination of the materials employed in the generation of the hydrogen gas used for inhalation. The sulphuric acid was found to be mixed with an especially large proportion of arsenic, and the zinc also contained this noxious impurity.—*Berlin. klin. Woch.*, *May* 3, 1880.

THE TREATMENT OF EPILEPSY.—A valuable paper on this subject, by M. Hambursin, of Namur, is published in the *Bulletin de l'Académie Royale de Méd. de Belgique*, No. 2, 1880. As epilepsy is most frequently developed in anæmic persons, the author first insists on the necessity of a strengthening, nitrogenized diet, with wine in tonic doses, and some form of iron. Exercise in the open air, and the avoidance of all things that might excite the passions, are also recommended. If the disease be supposed to be due to the pressure of a tumor on a nerve, to alcoholism, lead-poisoning, or syphilis, to uterine maladies, or any other curable affection, the first indication of course is, if possible, to remove this cause. Blisters and local bloodletting were at one time much in vogue, but are permissible only when the epilepsy is symptomatic of an encephalitis, or when an idiopathic epilepsy is accidentally complicated with symptoms of cerebral inflammation. The treatment of the aura is now generally abandoned, because it has been demonstrated that the aura, in the rare cases in which it exists, is almost always only a peripheral symptom of central disease. Still, good results have occasionally been obtained from the application of blisters, ligatures, etc., to the point whence the aura starts. Many remedies have been employed with a view to lessen the irritability of the nervous system, the most important of these being the oxide and the salts of zinc, nitrate of silver, and especially bromide of potassium. With the preparations of zinc, the author has never had any success at all, and he has not used nitrate of silver on account of the discoloration of the skin it produces. Bromide of potassium is given in doses of from half a drachm to three drachms. Voisin recommends that the doses be sufficient to abolish the reflex nausea caused by tickling the pharynx, and states that he has cured half his cases of recent epilepsy since adopting this plan of administration. On the other hand, M. Hambursin states that he has used the large doses of the bromide for fifteen years, and that he has never known them to produce a cure, although many of his cases were greatly improved. Unfortunately, the bromide, when given in large doses, is liable to cause gastric pains and bromism, and when used for a long time, even in connection with iron, it leads to the development of a decided anæmia. In view of these facts, M. Hambursin thinks that it is wrong to persist with the administration of the bromide when it does not rapidly produce a marked amelioration. Another indication for treatment is to prevent the vascular spasm which causes the encephalic anæmia of the initial stage of the attack. For this purpose the galvanic current has been employed with the view of acting directly on the cervical sympathetic. Some success has followed its use, but as a rule it has proved unsuccessful, probably because of the transient nature of its action on the nerves. The same effect has been sought for with the aid of drugs that act on the vaso-motor nerves, such as valerian, belladonna, curare, and cocculus indicus. Of all these, M. Hambursin has found the last the most efficacious, but he has found it necessary to give it in much larger doses than are recommended by M. Planat, who first employed it in the treatment of epilepsy. He employs the tincture, and begins with a dose of ten drops morning and evening, increasing by two drops daily until he has reached the dose of sixty drops; then he increases by ten drops a month, until the dose is a hundred drops. If the attacks have ceased by this time, he continues with this dose; if not, he does not hesitate to increase the dose to a hundred and fifty drops, and would not hesitate to give still larger doses, if necessary. The use of the remedy should not be interrupted, for fear of impairing its effects. The cocculus indicus produces symptoms of cerebral congestion; hence, it is proper to conclude that, when administered in the above manner, it keeps the cephalic vessels in a state of permanent relaxation, and thus prevents the vascular spasm which produces the sudden anæmia of the brain, the fundamental condition of the initial stage of the epileptic attack. M. Hambursin concludes his paper with reports of six cases of long-standing and severe epilepsy, all of which had been treated without success with large doses of bromide of potassium, and in all of which the attacks have ceased entirely under the cocculus indicus treatment.

Dr. Mikeleff, of St. Petersburg, states (*Gazette des hôpitaux*, April 6th) that until recently epilepsy was regarded as incurable in Russia, but that of late years it had been treated with great success with Henry Mure's syrup of the bromide, which seems to have been the only chemically pure preparation of the salt imported into that country. He asserts that, in the course of a large practice as a specialist, he can count positively two hundred definitive cures, as well as a large number of cases of improvement in which the attacks were suspended for a year or eighteen months, all of which cases were treated by Mure's syrup.

APPARATUS FOR THE REDUCTION OF UTERINE DISPLACEMENTS.—Dr. Verrier, of Paris, describes a new apparatus designed to secure instantaneous reduction of displacements of the uterus, which he has employed with success in a number of cases. It consists of a seat with stirrups, and a movable back which can be let down until its upper border touches the floor, so as to form any desired angle with the seat. The back is supported by two strong wire springs, which are attached above to a bar of wood secured to the ceiling of the room. To the centre of this bar is also secured a lever of the first order, and by means of a cord attached to its long arm the patient can let herself down and raise herself up without the slightest jarring of the body. It is in this employment of the lever that the chief advantage of the apparatus lies. It is a well-known fact that, in the reduction of malpositions of the uterus, great assistance is derived from raising the patient's hips sufficiently to take the weight of the intestines and viscera off the uterus, but this advantage is often lost by the jarring of the body in the effort to regain the natural position. This jarring is itself often sufficient to cause an immediate return of the displacement. Dr. Verrier claims that the use of the lever in his apparatus entirely prevents this jarring, and that, when the body is raised quietly and gently with its help, the intestines fall into their normal position in front of and behind the replaced uterus, and aid in retaining it in position. The further treatment after replacement consists in the use of tonics and local and general stimulants. The apparatus is, of course, only intended for use in cases uncomplicated by adhesions or peritoneal thickening from previous inflammation.—*Gazette obstétricale*, June 5, 1880.

New Treatment for Relaxation of the Membrana Tympani.—Dr. McKeown, of Belfast, recommends the application of contractile collodion to the membrana tympani in cases of relaxation of that membrane, with a view to restore tension. He states that the collodion contracts the membrane to a greater or less extent while it remains adherent, and also exerts a permanently beneficial influence on the relaxation. He reports the following case as an example: The patient, a woman, æt. 41, had been under his care from time to time for three years for catarrh of the drum and its results, and had been treated by the usual methods. With the left ear she heard the voice (moderate tone) at a distance of three feet, but the hearing varied much. The noises in the ears were of the most distressing kind. Between the upper part of the handle of the malleus and the posterior wall of the meatus, there were a number of depressions, which became bulgings on inflation of the drum by Valsalva's method. Collodion was freely applied to the drum, and the hearing at once improved and continued steady. She could hear the voice (moderate tone) at a distance of eighteen feet, and the noises ceased. The confusion of voices and the subjectively unnatural character of her own voice, which had previously annoyed her greatly, disappeared. The depressed part became quite flat. About three months later the layer of collodion seemed loose, but it was only after some difficulty that it was removed by syringing. The hearing remained good, and the depression had disappeared, probably owing to the long-continued bracing up; but, as the membrane still seemed too lax, another coat of collodion was applied two days afterward. At present the hearing is stationary, the relaxed part has its normal tension, there is not the slightest depression at any part, and the membrane has become, perhaps, more than usually transparent. The patient has not had a single unpleasant noise since the first application, fifteen months ago. The collodion was applied only twice, and no other treatment of any other kind was employed.—*Dublin Journal of Medical Science*, June, 1880.

Numerical Changes of the Blood-Corpuscles in Inflammations.—In a note to the *Académie des Sciences*, M. Hayem details the results of his investigation on this subject. In a state of health the number of the white corpuscles varies with the age: during the first 48 hours of life the average number is 18,000; at the end of the first month it is 8,000; in children from several months to four years of age it is 6,000; in adults and old people it is 5,000. The number is the same in women as in men, except that there is generally an increase of from 1,000 to 2,000 during the menstrual epoch. During the existence of inflammatory processes, however, the white corpuscles increase greatly in number. In 65 observations M. Hayem found that the number varied between 7,000 and 36,500. The first figure was found in a case of slight, almost apyretic erysipelas of the face; the second in a double caseous pneumonia with cavities. In the majority of the observations, the number varied between 15,000 and 20,000. In general, it might be said that the number was greater in direct ratio to the activity of the inflammation. The numerical variations of the red globules were so irregular that it was found difficult to formulate any law for them. Still, it seemed to be demonstrated that an acute inflammation of from eight to ten days' duration, such as a pneumonia, almost always caused a loss of from 200,000 to 1,000,000 red globules per cubic millimetre. When an acute inflammation was followed by a rapid recovery, the number of red corpuscles became physiological in a few days, but when it terminated in a chronic condition, this restoration was not observed. The number of the hæmatoblasts, which is in the normal state 225,000, presented little change during the acute stage of inflammation. The only points of any importance are that it attained its minimum at the moment the inflammatory affection reached its crisis, and then began at once to increase rapidly and progressively, reaching its maximum, which was two, three, or almost four times greater than the normal figure, within two or three days in the distinctively acute cases. This accumulation of hæmatoblasts, which constituted by its constancy and intensity a sort of hematic crisis, was intimately connected with the evolution of the lesion; it was observed in the fatal cases as well as in those that terminated in recovery, provided resolution had set in.—*Le Courrier médical*, March 27, 1880.

The Digestive Action of Papaya Juice.—Last year, M. Bouchut reported the results of some experiments with the juice of the carica papaya, which proved that papaïne, the digestive ferment contained in it, forms, with albuminoid substances (fibrin, gluten, raw meat, milk), combinations having all the characters of the assimilable peptones. He has since continued these experiments with living tissues, both healthy and pathological, such as cancers and adenomas, and has arrived at some interesting conclusions, which are embodied in a paper recently read before the *Académie des Sciences*. These living tissues are digested, and converted into peptones by the papaïne, just as is the case with dead tissues. In three cases of cancer of the breast, and one of secondary cancer of the inguinal glands after castration, injections of papaïne were followed by softening of the large, hard tumors. The liquid product drawn by aspiration from one of these tumors, which was as large as a fist, was examined by M. Henninger, and seemed to be a veritable peptone. In one of the experiments a large frog was partly skinned, and immersed alive in a jar filled with papaya juice diluted with four parts of water. In twelve hours the animal was dead, in twenty-four hours it was partly digested, and at the end of two days nothing was left of it but the skeleton. M. Bouchut thinks that these experiments justify the conclusion that papaïne is capable of digesting all the organized tissues, even while living. It is, according to him, a *vegetable pepsine*, which acts upon living tissues in the same way as on albuminoid substances deposited in the stomach or in a laboratory jar.—*Le Courrier médical*, March 27, 1880.

Removal of the Thyroid Gland.—M. Tillaux reports a case in which he removed the thyroid gland successfully. The patient, a woman twenty-nine years of age, had a goitre as large as a child's head. The tumor caused severe attacks of suffocation at night, and attacks of violent palpitation of the heart. Her vision was impaired, but there was, strictly speaking, no exophthalmia. The operation was very tedious and difficult, and the hemorrhage was alarming. The operation was, however, entirely successful. After the tumor was removed the attacks of suffocation ceased at once, and all the other morbid phenomena disappeared likewise.—*Le Courrier médical*, May 1, 1880.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, August 21, 1880.

THE PHYSICIAN AND PHARMACIST.

In the present issue we publish several letters which will doubtless be read with some interest in connection with editorial remarks made in recent numbers of the Medical Record, upon the general subject of which they treat. The correspondents, as might have been expected, view the situation from different standpoints, but each, in his own way, endeavors to do the best for his side of the argument. It is somewhat reassuring, in counting upon the chances of a proper and mutual understanding, to notice that the real points of difference are not absolutely irreconcilable. In other words, considering the views presented and the facts set forth by our correspondents, we were not far out of the way in our judgment of the situation. But it is not our purpose to go over old ground, but, by commenting upon some of the suggestions thrown out by our contributors, to extend the discussion of the general subject. In so doing we shall not attempt to follow any logical order, but take up the different points as they are presented by the writers.

Concerning the impropriety of physicians or druggists answering the questions of patients as to the contents of prescriptions, or the character of the medicines prescribed, a great deal can be said. On general principles, it is not only not necessary for the patient to know the remedy he or she is taking, but such knowledge is sometimes prejudicial, if not positively harmful. There is, of course, a temptation to appeal to the intelligence of our patients, with the idea that we can the better retain their confidence; but this can be done in another way than by discussing the nature of the remedies to be used. The opposite is, however, so often done, even by the leading practitioners, that it is growing into a monstrous abuse of professional privilege. Not only have some consultants the habit of giving clinical lectures in their offices, to patients, but the latter are informed as to the medicine and its dose, which are indicated in the particular case. Is it any wonder that the patient considers himself a party in the consultation, and acts accordingly? Consequently, in the course of the discussion, when it is proved to the satisfaction of the patient that he understands his case better than does the doctor, the latter is voted an ignoramus, and is discharged. But, even when this is not the case, and the physician is able to maintain his position as principal adviser, the next medical attendant may not be so fortunate. Aside from not knowing the patient's peculiarities as well as the previous adviser, he is in entire ignorance of the remedies which have been made by mutual agreement so eminently satisfactory to the patient. No one can deny that the second attendant operates at a disadvantage, and that he is, very unjustly, made the subject of invidious comparison.

It is sometimes tempting human forbearance to be informed by the patient that Dr. A. never believed in bromide of potassium, carbolic spray, ergot, or pilocarpine, when Dr. A. is clearly in the wrong. Still worse is it to be compelled, under such circumstances, to explain the case to the patient, and at the same time leave the impression upon his mind that medicine is an exact science. But the necessities for such explanations seem to be growing upon us day by day, because the patient is being educated to believe that he has a right to know what he is taking.

Why this should be so it is difficult to explain, save upon the assumption that many physicians are careless with the remedies they employ, and are content to give general directions as to doses and the like, merely to save what appears to be the trouble of prescribing scientifically. How often the patients are told to take so many grains of quinine night and morning for malarious troubles, or so much laudanum when the pain appears, so much digitalis when palpitation shows itself, etc., etc., thus virtually leaving them with the detail management of their own cases. This is not what it should be. It is beginning at the wrong end, and cannot fail to work disastrously against the patient as well as against the profession. The people need education on medical topics, but cannot be expected to understand how to treat disease, nor to learn the real value and application of remedies. It is much better that these points should be mysteries to them, rather than that they should be tempted to accept that "little learning" which we have the best authority for saying, "is such a dangerous thing."

It is safe to say that where one patient may be actually benefited by knowing the remedy he is taking, ninety and nine are positively harmed by it. The exceptional cases of benefit are those in which marked idiosyncrasies exist, in which it is necessary for the patient to know that certain medicines are positive poisons to them. The rule of benefit to the sick one is altogether on the side of ignorance of the remedies prescribed. There is something in the efficacy of a blind faith in medicines which cannot be gainsaid, and there is no reason why the therapeutist should not take advantage of it.

But in fear that we may, by further pursuing this part of the subject, drift into the discussion of self-evident propositions, we hasten to refer to other matters bearing upon the general question under consideration. The charge, by one of our correspondents, that physicians create a demand for proprietary articles, is a serious one. We are much inclined to the belief that his experience with prescribers has been exceptional, and that his remarks by no means apply to the profession as a body.

It is hardly an excuse for counter-prescribing, for selling patent medicines, and the like, to say that the prescription business does not pay. No physician hinders a pharmacist from making a living profit on the compounding of a prescription, if the pharmacist shows a disposition not to interfere with the functions of the prescriber. As we have said before, in compounding medicines, skill will always be in demand, and none are better able than the members of the medical profession to appreciate the fact.

No language is too strong to use against interference, by word or deed, on the part of compounders of prescriptions. The horse-medicine affair alluded to by one of our correspondents has more than a ludicrous aspect, as also the case in which the obliging druggist is ready to volunteer instruction to his anti-quinine customer. It must be admitted that there is a strong tendency with some physicians to dispense their own remedies. This appears to be a retaliatory measure in lieu of the prevalence of counter-prescribing by apothecaries, and of their practice of repeating prescriptions without authority. The hint to cease both these practices is a very broad one, and should be considered by the compounders from a business point if from none other.

RAPID BREATHING AS A PAIN-OBTUNDER.

In 1875 Dr. W. G. A. Bonwill, a dentist of Philadelphia, discovered that by causing his patients to breathe rapidly for a few minutes, the sense of pain was often so obtunded that he could extract teeth without causing any discomfort. The matter was, soon after this, taken up by Dr. Addinell Hewson, who made a favorable report of his experience with the method, at the International Medical Congress in 1876. Not much interest was excited, however, and the subject was virtually dropped.

At a recent meeting of the Philadelphia County Medical Society, papers upon rapid breathing, as a means of inducing analgesia, were read by Dr. Benjamin Lee and by Dr. Bonwill. Considerable discussion followed. A perusal of the papers and discussions leads to the conclusion that there may be something of considerable practical value in Dr. Bonwill's discovery. At any rate, as it is a thing which can be easily tried without risk to any one, we give briefly the facts regarding it.

In some cases it is necessary, when rapid breathing is to be undertaken, to have the patient sitting in a chair. The most favorable position for him, however, is that of lying down on the side; and it is generally best to throw a handkerchief over the face, so as to prevent the patient's attention from being distracted. He should then be made to breathe at the rate of about one hundred respirations per minute. The direction best given is to "blow out" in rapid puffing expirations. At the end of from two to five minutes, the patient continuing his rapid breathing all the time, teeth may be drawn or incisions made, and there will generally be an entire or partial absence of pain, which will last thirty seconds or more. The sense of touch is not affected, nor is consciousness gone. When the breathing is first begun the patient may feel some exhilaration; following this comes a sensation of fulness in the head or dizziness. The face during this time becomes at first flushed, but later, according to Dr. Hewson, it is pale or even bluish. The heart beats more feebly and somewhat faster than normal. We are told that this phenomenon of analgesia is produced in females more readily than in males, and in those of middle age more easily than in the young or old. Children under ten can rarely be made to breathe properly. In cold, clear air a longer time is required than when it is warm.

Regarding the practical uses of the method, it is claimed that it may supplant ether, chloroform, or nitrous oxide in dentistry, minor surgery, and often in obstetrics. In the latter case it is especially applicable when the forceps are to be used. A case of tracheotomy and one of ischio-rectal abscess were related, in which analgesia was successfully produced by rapid breathing. The ordinary anæsthetics, when employed for major operations, can be made more effective by combining with them rapid breathing. According to Drs. Garretson, Hewson, and Kite, it takes from one-half to three-fourths less of the liquid anæsthetics to produce insensibility when the administration is supplemented by rapid breathing. The after effects are also less nauseating and unpleasant.

As regards the possible dangers, it is denied that there can be any. Dr. W. R. D. Blackwood, however, stated that he had tried the method on a somewhat hysterical patient, who kept on breathing rapidly for so long a time that he was somewhat alarmed.

The theories of how the rapid breathing acts in thus obtunding pain are as yet unsatisfactory. Dr. Bonwill and Dr. Hewson, its two especial champions, entirely disagree in their attempts at explanation. Dr. Bonwill assigns three causes: 1st, the diversion of the will-force caused by the rapid voluntary muscular action; 2d, the specific effect of carbonic acid gas set free from the tissues, caused by the throwing into the lungs five times the normal amount of oxygen; 3d, hyperæmia, due to the excessive amount of air passing into the lungs and causing a damming up of the blood in the brain. The main point of the theory is that rapid breathing produces a hyperoxidation of the blood, which sets carbonic acid free in the tissues. Dr. Hewson, on the other hand, believes that there is a diminished oxygenation of the blood during rapid-breathing, and that the excess of carbonic acid which results poisons the nerve-centres and causes analgesia.

It is unnecessary to discuss these theories. The one is crude, and neither is sufficient. As far as the method itself is concerned, it seems to be well proved that analgesia to a greater or less extent can be obtained by it. Its practical usefulness is not so well established. A good many failures have occurred, and a large amount of evidence is yet to be obtained in order to show its reliability. The method is simple, however, and there ought not to be any trouble in speedily determining its exact value.

Reviews and Notices of Books.

NEURALGIA: ITS NATURE AND CURATIVE TREATMENT. By THOMAS STRETCH DOWSE, M.D. New York: G. P. Putnam's Sons. 1880. 8vo, pp. 194.

THIS book is essentially a clinical treatise on neuralgia. The author makes no attempt to discuss the nature of the disease or to suggest a morbid anatomy for it. After nine pages of introduction, the subject of treatment is taken up, and this occupies the rest of the book. It is divided into a chapter on the treatment of neuralgias in general and one on special neuralgias. Numerous illustrative cases are given. The book will form a very useful and complete guide to the therapeutics of the disease. It is a work designed especially for the busy practitioner, and will doubtless fulfil its purposes in this direction.

If we were to make any criticisms, they would be that the author has failed to inform himself upon what American physicians have done for the therapeutics of neuralgia. The experiments of Seguin and others demonstrating the value of aconitum, for example, seem to be entirely unknown. We cannot agree with Dr. Dowse in his constant recommendations of alcohol and opium for neuralgics. If we may judge by his reported cases and other statements, a large majority of his patients are put upon these drugs—until cured; and all the cases reported are cured with a suspicious uniformity. Dr. Dowse evidently does not believe that anything can be taught by his failures. The author is as heroic in all his doses as he is with opium; however, he is in accord with most neurologists. Thus, chloral is given in ℈ij. to ℈iv. doses; atropia, gr. $\frac{1}{20}$; tinct. gelseminum, ʒj.; chloroform, ʒj., etc. Such doses often need to be given, but they should be recommended with a caution. The book is a model of typographical neatness.

FOURTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF WISCONSIN, 1879.

THE State Board of Health of Wisconsin has done exceptionally good work since its organization, and the present report contains much valuable matter. Besides giving an account of the prevalent diseases and general sanitary condition of the State, a number of articles upon special topics are contributed by members of the Board. The subject of the school-house and school-system is discussed more than anything else, and, judging from the facts given, such discussion is much needed. After showing a number of sanitary defects in the school-buildings, the report states that in at least seven per cent. of these there are no privy accommodations at all, while in twenty per cent. boys and girls, promiscuously, are compelled to make use of the same apartment. Furthermore, in fifty-eight per cent. the privies are entirely unscreened from the weather and from observation. If, as quoted in the report, the true test of a nation's civilization is to be found not in the splendor of its public buildings, but in the neatness of its privies, Wisconsin cannot claim to rank very high. There is no reason to suppose, however, that she is worse than many other States. Papers by Prof. T. C. Chamberlain, on Adulterations of Food, and by Dr. G. F. Wilter, on Ground Air, embody some very useful facts. The Board reports an increase in its local correspondence and a wider appreciation of the value of its work.

SECOND ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF RHODE ISLAND FOR 1879.

WE have seen no report from a State health board which contains such full and well analyzed vital statistics as does this. The tables with comments embrace a large portion of the report, and are too voluminous for any adequate criticism here. The State Board has under its supervision the contagious diseases of animals. It has done good work in ridding the State of glanders and in preventing the spread of pleuro-pneumonia. An essay by Dr. Oliver C. Wiggin, on the Artificial Feeding of Infants, to which was awarded the Fiske Fund Prize, is incorporated in the report, and forms a valuable part of it. The Ventilation of School-Houses, The Sewerage of Dwellings, and Color-Blindness, are subjects that are well discussed. The volume is creditable to the Board, and should have a more than usual local value.

ELEVENTH REPORT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS, for the six months ending June 30, 1879.

THE present report is made up chiefly of circulars upon Disinfection, House-Drainage, The Care of Young Children, Boards of Health, and Registration. All these are excellent documents, but are now pretty well known. The report covers only six months, as on June 30th its organization ceased, and the new Board of Health, Lunacy and Charity took its place.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF TENNESSEE, Forty-seventh Annual Meeting, Knoxville, April 6, 7, 8, 1880.

THE Tennessee Medical Society has shown remarkable enterprise in getting its proceedings published within three months of the date when they took place. We commend the example to other societies. A report of the proceedings of the Society was published in THE RECORD at the time of their occurrence, and we can give but a brief space to the present volume. It contains a good many practical papers, but there is no evidence of scientific work, and the contributions on the whole are rather cheap. The book bears on its cover the seal of the Society, inscribed with the legend: "The Science of Medicine an Important Part of the Science of Humanity." We don't know exactly what is meant by the "science of humanity," but presume it has something to do with the lady with very attenuated extremities who sits in her night dress just above the Humanity. Whatever the meaning, the motto is a very weak one, and we advise the Society to have it changed.

Reports of Societies.

MINNESOTA STATE MEDICAL SOCIETY.

Twelfth Annual Meeting, held at Albert Lea, Minn., June 15 *and* 16, 1880.

Dr. A. C. Wedge, of Albert Lea, President, in the Chair.

Tuesday, June 15th—First Day.

The President congratulated the members of the Society on their success in establishing a permanent State Medical Society, and alluded to the rapidity with which the population of the State was increasing, and to the improved travelling facilities for reaching places at which meetings of the Society were held. He also referred to the value and success of the State Board of Health, and said it was an outgrowth of the State Medical Society.

Dr. C. N. Hewitt, Chairman of Committee on Practical Medicine, made his report.

CHRONIC CONGESTION OF THE UPPER AIR-PASSAGES.

Dr. Owens, of St. Paul, read a paper on "Chronic Congestion of the Upper Air-Passages." He stated that in his experience chronic Bright's disease was an occasional cause of this condition, and that although chronic degenerative changes in the parenchyma of the kidney did not always cause diseases of the mucous membrane of the air-passages, yet it acted as an exciting cause when there existed a constitutional tendency to congestion of the mucous membranes, and increased the severity of the disease when already present. He considered the strumous diathesis a most important predisposing cause. With regard to treatment, he suggested that it should be both local and constitutional. Where the strumous diathesis was present, cod-liver oil, iron, etc., was very useful. In those cases resulting from chronic Bright's disease, saline diuretics, iron, cod-liver oil, etc., were indicated. Hot water injected with a post-nasal syringe and gargles were of great value. He also recommended frequent applications of mild astringents.

Dr. D. W. Hand, of St. Paul, read a paper on "Diseases of the Tonsils," giving a detailed account of the character and treatment of each.

EMPYEMA.

Dr. Talbot Jones, of St. Paul, reported a case of empyema, which occurred in a boy eleven years of age, with no hereditary taint. In March last the patient received an injury to his left chest. A fortnight after the injury he began to suffer from loss of appetite, shortness of breath, and pain in the left chest. He had a succession of rigors. He soon became very weak. When Dr. Jones saw the child it was in a desperate state, and would, in all probability, have died in two or three days, had not an operation been at once performed. A physical exploration showed complete displacement of the heart, which was beating on the right side of the chest. There was marked bulging outward of the intercostal spaces as far up as the second rib, on the left side. Absolute flatness on percussion, and absence of the respiratory murmur when the ear was applied to the chest. He decided to perform paracentesis thoracis, and introduce a drainage-tube. He made the puncture in the seventh intercostal space, midway between the spine and sternum. Pus, to the amount of two quarts, was removed. He would allow the pus to run for a minute, then plug the canula for fifteen minutes, then allow it to run again for a minute, and so on for an hour. This was in order to permit the compressed lung to expand. For a drainage-tube he used an English catheter. The pleural cavity was washed out twice a day with a three per cent. solution of carbolic acid. Under tonics and a general supporting treatment, the patient made a good recovery. For five months after the operation, secretion and escape of pus went on. He then withdrew the tube and allowed the wound to heal.

At the present time, eight months after the operation, the boy continued in perfect health.

DIPHTHERIA.

Dr. Samuel D. Flagg, of St. Paul, read a paper on "Diphtheria." It consisted of a clinical report of four cases in his practice. He alluded to the period of incubation. In one case sudden death occurred, the cause of which he supposed to be heart-clot. His experience in these cases added weight to the opinion that throat diseases of various forms were prevalent during epidemics of diphtheria, and to the views of Hutchinson, that follicular tonsillitis was a near relation of diphtheria and may arise from it.

A CASE OF SO-CALLED WHITE CEREBRAL SOFTENING, WITH PARTIAL HEMIPLEGIA.

Dr. Talbot Jones read a paper entitled "A Case of so-called White Cerebral Softening, with Partial Hemiplegia."

J. T., aged sixty years, never suffered from syphilis, was not addicted to alcoholic indulgences, and had never received a blow on the head. He lived alone on a farm, did his own work, and prepared his own meals.

Hemiplegia of the left side developed so gradually that it was impossible for the patient to state when his attention was first drawn to the commencing palsy. He declared he had suffered from more or less headache for months, from tinnitus aurium, but never from vomiting. He never fell to the ground suddenly unconscious. The partial paralysis was accompanied by numbness or fomication. The palsy chiefly affected the lower extremities. It was with great difficulty that the patient could be understood. There was difficult articulation, and he jumbled his words in such a manner that one was often obliged to guess his meaning. Oftentimes, in the midst of a sentence, he would hesitate or stop, as though he had lost the thread of his discourse, or could not command the proper words to express his ideas. When well he was noted as being a quiet, reserved man, but it was now noticed that his emotional nature had undergone a decided change. He would be gay and mirthful without any adequate cause.

There was marked mental decay, progressive deterioration of memory, defective ideation, and impaired volition.

The face was not involved, and when the tongue was protruded it did not point toward the paralyzed side. In walking it was observed that the left foot was dragged after him. There was present a certain rigidity of the muscles—chiefly of the leg—but to a less extent observed in the arm also. The diagnosis was arrived at by exclusion. It was necessary to exclude *congestion, cerebral anæmia, abscess, hardening*, and *exhaustion of brain-power*, encountered among literary or professional men engaged in laborious intellectual pursuits. These were taken up in turn, and the disease under consideration carefully differentiated from them. The *treatment* in a generous diet and tonics of iron, strychnine, phosphorus, etc. The patient improved physically, but not mentally. It was impossible to arrest the progressive mental decay. The patient died recently in England, his former home, whither he had gone by the doctor's advice.

Dr. D. W. **Hand** reported a case of locomotor ataxia.

Dr. **Emery** read a lengthy paper upon the "Metric System of Weights and Measures." He compared this system with the one now generally in use, and showed the advantages of the former over the latter. He urged the members to investigate this subject, and to write prescriptions according to the metric system.

CASE OF OVARIAN TUMOR.

Dr. D. W. **Hand** reported the following case of ovarian tumor:

Miss S., aged twenty years, had been in delicate health for about two years, but was able to do light work.

January 21, 1880, she was admitted to St. Luke's Hospital. On examination a fluctuating tumor was found pressing down between the rectum and vagina, and extending nearly as far as the perineum. The abdomen was somewhat distended, but soft, and there was a fulness in the left inguinal region. Drs. Hagan and Wharton saw the case with me. The diagnosis was ovarian tumor presenting in this unusual position. To make our diagnosis more certain we aspirated the tumor, and drew off six ounces of a clear albuminous fluid, about as much more coming away after the withdrawal of the needle. A second fluctuating cyst could now be detected still higher up, and it was now evident that the tumor was *multilocular*.

The patient remained comfortable for three days. At this time, while she was having an action from the bowels, and was sitting upright on the vessel, contrary to positive orders, one of the cysts ruptured into the intestines, and there was quite a copious discharge of the same straw-colored fluid that had been drawn away with the aspirator. Some of the fluid evidently escaped into the peritoneal cavity—for almost immediately she had a chill, and all the symptoms of peritonitis began to manifest themselves. Large doses of opium were of no avail. The inflammation soon spread over the entire abdomen, and death took place on the fifth day. This is the second case of ovarian tumor, presenting through Douglas's fossa, that had come under my observation.

DEATH FROM EXPULSION OF UTERINE FIBROID.

Dr. E. J. **Davis** read a paper entitled "Death from Expulsion of a Musculo-fibroid Tumor of the Uterus." He first reported this case in the Transactions for 1878, but it had a subsequent history. On February 24, 1879, eleven months after the first operation for removal, he was called on again by the same lady to remove a similar tumor, which he did in the same manner as in the first operation. The tumor resembled the former one in shape, character, size, and place of attachment. After removal a careful search was made for any shreds which might be left attached to the uterus, but none were found. The patient came again on August 7th, five and a half months from the time of the last appearance. It was found on examination that the tumor had reformed. On the same day, August 7th, it was removed by a method similar to the one that was employed for the removal of the previous two tumors. This resembled, in all respects, the other two. On examination after removal an enlargement was found in the hypogastric region. The patient soon began to have pains identical with labor-pains, which were very severe and continued till the tumor was expelled and lay between her thighs. This uterine effort caused her great nervous excitement and prostration. Owing to her condition, and its being night, operative interference was put off till the following morning. But the patient grew weaker and weaker, and died before noon the next day. Toward evening a post-mortem examination was made, and the pedicle was found attached to the fundus uteri. All the organs were normal. The tumor weighed five and a quarter pounds. The two latter tumors attained their growth in four and a half months.

POST-PARTUM HEMORRHAGE.

Dr. **Daniel Leasure**, of St. Paul, read a paper on Post-partum Hemorrhage, in which he took the ground that it was a true collapse due to sudden failure of inervation in the ganglionic centres, following the supreme act of parturition, similar to the failure of the heart which takes place in certain acute diseases, which also arose from defective inervation by the ganglionic system. On the assumption that all the acts of purely organic life are entirely subject to that system of nerves, he argued that any failure of function in an organ dependent on it for inervation, must of necessity cause a temporary lapse of function, or lesion in that source of inervation, and that to suspension or only partial action of the nerve-centres of organic life, and not to the uterus *per se* was due the suspension of contractility in the recently emptied uterus.

He drew attention incidentally to the fact that natural labor was not necessarily accompanied by pain, and instanced the painless delivery of women in the purely savage state who are found at the capes and in Australia, and also the absence of pain in purely wild animals, and suggested that the advanced development of the cerebro-spinal centres in the civilized woman destroyed or modified the original coordination between the two systems of nerves, as they existed in the natural wild woman, and which accounts for the painful labor in the civilized woman. Upon this hypothesis he based his treatment of post-partum hemorrhage, and showed that all applications made to the uterus itself acted as irritants, such as manipulations of the organ, either through the abdominal wall or in the cavity itself, or hot or cold irritant substances applied to the cavity, which by reflex action upon the ganglionic centres, brought about a return reflexion of nervous energy that caused the organ to wake up from its lethargy, and by contracting close up the open lacunæ of the placental wound.

He also mentioned instances of death occurring from post-partum collapse without more than the normal amount of blood having been lost, and he argued that in these cases the organs of circulation and respiration were involved in the results of the collapse.

With regard to treatment he mentioned the usual irritants and manipulations applied to the uterus externally and internally, and recommended the use of vinegar as an irritant to bring about reflex action of the ganglionic centres, so as to cause them to act on the dormant uterus. Hot water injected into the cavity of the uterus, was, in his opinion, the best of all irritant agents. The water must be hot, warm water was useless. In support of this he mentioned the benefits which result from the use of hot water as a so-called styptic in ordinary traumatism. In the ordinary sense of the word, heat was not a styptic, but it was a stimulant to the nervous fibrils in the wound. and thus, by reflex action through the vasomotor system, caused the torpid walls of the blood-vessels to contract.

The faradic current he instanced as the most effective external irritant. The current must be directed through the chief centres and plexuses of the sympathetic, through the great trunks of the cord of the sympathetic and through the uterus.

For internal use the best remedies were ergotin and emetin. He showed the influence of these drugs on the centres of organic life and their special action on the vasomotor system. These ought to be given persistently, coupled with ordinary and extraordinary effects by manipulation and irritants. He preferred their administration hypodermically, for given in this way they were more prompt in their action. As a prophylactic measure he recommended a dose of ergot before delivery, for it could do no harm and might ward off a danger none the less terrible because frequently encountered.

ORGANIC HEART DISEASE.

Dr. T. F. Jones read a paper entitled, Case of a Patient with Organic Heart Disease attacked and beaten by Two Men. His Death Five Months after. Coroner's Inquest. The Men Arrested and their Subsequent Examination before Judge Flint. Interesting Medico-legal Questions Involved.

(This was quite a lengthy paper and only a short abstract can be given.) The patient was thirty-five years of age, and by occupation a horse-trainer. He never suffered from acute rheumatism. About five months before his death he was attacked and beaten by two ruffians. Up to the time of his assault the patient considered himself perfectly healthy. He had never had his attention drawn to his heart by any unusual sensations in it.

About six weeks after the assault he began to be troubled with dyspnœa when he exerted himself, with oppression over the præcordia, palpitation and other symptoms of heart disease. The symptoms increased in severity as time went on. The patient was first seen by Dr. Jones about six weeks prior to his death. He was, at the time of Dr. Jones's first visit, in a paroxysm of dyspnœa, and quite cyanotic. He experienced a frightful sensation of being smothered; had pain over the heart and stomach, and also suffered from palpitation of the heart and a most troublesome cough.

On examination, it was found that there was dulness over the left lung. The area of superficial cardiac dulness was increased to a very great degree. The heart beat tumultuously. There was observed a powerful heaving movement of the whole left chest at each ventricular systole. The rhythm of the heart was altered and the organ beat irregularly and spasmodically. The apex-beat was in the seventh intercostal space, and was displaced downward and laterally some four or five inches beyond its normal location.

There was predominant hypertrophy of the organ as shown by the powerful impulse against the chest-walls at each ventricular systole. With the stethoscope over the apex a loud and rough endocardial murmur was heard synchronous with the systole of the ventricles. This murmur was not propogated into the carotids, but could be heard laterally around the chest, and very distinctly under the lower angles of the scapula. At the base of the heart there was a murmur indicative of some aortic regurgitation. There coexisted then, in this case, aortic and mitral regurgitation.

The man grew worse in spite of treatment and died five months after he was assaulted by the two men.

The day following his death the coroner held an inquest with a view to investigate whether or not death was hastened by the assault.

Drs. Owens and Jones made the autopsy. The body was very much bloated, owing to post-mortem changes and to the general dropsy which had set in a short time previous to death. The left lung was found contracted, owing to pressure from the enlarged heart. The heart itself was enormously enlarged, weighing just twenty-two ounces. The endocardium was injected and bore other evidences of inflammation. On one of the aortic semilunar valves was seen a patch of atheroma. There was also slight circumscribed pericarditis. The valves were in a condition which explained the murmur heard during life.

The men who committed the assault were arrested and subsequently examined in the municipal court of the city on the charge of manslaughter. During the trial several important and interesting medico-legal questions arose, and it is to be regretted that they cannot be given here without extending this paper beyond reasonable limits. No possible connection was proven between the injuries and the heart trouble.

Evening Session.

The evening was devoted to the discussion on diphtheria. There was a general exchange of views as to the etiology, morbid anatomy, prevention, and treatment of this disease.

Drs. Leasure, Davis, Jacoby, and Berry took the most prominent part in the discussion.

Wednesday, June 16th—Second Day.

Dr. E. J. Abbott, of St. Paul, Chairman of Committee on Surgery, made his report.

Dr. S. Blood, of Owatonna, read a paper entitled: "Amputation at the Knee-Joint for Senile Gangrene," founded on the history of a case.

NEW METHOD OF EMPLOYING PRESSURE IN TRAUMATIC ANEURISM.

Dr. B. R. Palmer, of Sauk Centre, reported a very interesting case of traumatic aneurism, with a novel method of employing pressure.

Dr. Palmer says: "I have lately used a method of applying pressure to an artery or any of the limbs, which, so far as I know, is new. It is effectual in controlling the action of the artery and accomplishes its object without any constriction or pressure of the soft parts, other than the spot at which the pressure is desired. It consists in the application of a broad band of plaster-of-Paris around the limb, with an aperture in it directly over the part of the artery to which you wish to apply the compress. Through this opening the compress is to be adjusted to the limb, and tightened and fixed in place by an elastic roller, which envelopes the limb outside the plaster shell, and is placed over the projecting portion of the compress, with sufficient tension to check the circulation in the artery to the desired extent. The idea occurred to me in the case of a traumatic aneurism of the femoral artery, in the thigh of a butcher, caused by the accidental plunging of a long, narrow, pointed butcher-knife into about the middle of the thigh. The patient is a very robust and muscular young man, and the aneurismal tumor, an hour or so after the accident, was very large—about four inches across and about three inches thick, with pulsation. I immediately applied the plaster-of-Paris band as before described, using a compress of cork covered with chamois, and projecting an inch and a half above the surface of the band. This was applied about two inches below the profunda, and the roller of elastic webbing brought around the band and over the projecting compress, tightening it at every turn until the pulsation in the tumor could be no longer felt. The pressure caused very little uneasiness, and was kept up for twenty-four hours, after which time it was removed, and pulsation in the tumor did not return. The compress was kept on, more lightly applied, for three days longer, when the patient, contrary to my advice, returned to his shop. The wound was inflicted on the 25th of April last, and on examination of the leg two weeks since, I found absorption complete and the patient well."

Dr. F. A. Dansmoor, of Minneapolis, reported a case of amputation at the knee-joint, performed on a boy seventeen years old.

Dr. James Davenport reported a case on which he had operated for stone in the bladder. The patient, a German, aged twenty-eight years, was seen in St. Joseph's Hospital during August, 1879. By means of the sound a stone was found, about one inch in diameter, situated a little to the right of the neck of the bladder. An attempt was made to grasp the stone, which failed; the lithotrite would not seize it.

It was then determined to perform lithotomy, the median operation being decided on. The usual incision was made, and after the knife had entered the bladder, the finger was passed in and two large stones were discovered. One of these stones was so large that it was found necessary to crush it before it could be removed. About the end of the third week the urine began to flow through the urethra, and in ten days from this time was under complete control.

While in the Pineries in May, 1878, the patient suffered from retention of urine brought on by a severe wetting. To relieve the retention, he passed up his urethra, in lieu of a catheter, a hollow reed of some kind which broke off in the bladder, and round the pieces left in the bladder the phosphatic salts were deposited.

MEMBRANOUS CROUP.

Dr. Talbot Jones read a paper on "Membranous Croup." He reported two cases. In one case, that of a girl, aged three years and two months, tracheotomy was performed. The operation was unusually bloody, and ligatures had to be placed on several large veins before the bleeding could be stopped. Respiration became less labored directly the tube was introduced, and when the child emerged from the influence of the anæsthetic it was at once seen that she experienced great relief. Whenever symptoms arose indicating obstruction, the canula was removed and cleaned. He had the little patient placed in a tent, the atmosphere of which was saturated with moisture by means of steam.

Everything progressed favorably for about thirty hours after the operation, but about this time alarming symptoms arose, showing an extension of the inflammation and obstruction below the tube. There was a sudden, sharp rise in the temperature, the symptoms became more aggravated, and the child died thirty-eight hours after the operation. The doctor believes that the operation lengthened the child's life for about thirty hours.

Dr. F. A. Dansmoor reported the following interesting case: Paul A., aged twenty-seven, about a year previous, fell to the ground from a platform on which he was working, the distance being seventy feet. Partial paraplegia was the result. During the next six months there was a slight return of sensation and motion, but he had no control over his urine. Several stones of different sizes formed in his bladder. One large stone lodged in the urethra, about one inch in front of the scrotum; it finally sloughed through and was removed by the patient, and it left a large fistulous opening.

Another stone became encysted in the anterior wall of the bladder, and then sloughed through, coming away just above the pubic arch, nearly in the median line.

Six months before the patient was first seen by Dr. Dansmoor, he had had the operation of lithotrity performed on him. When seen for the first time by the doctor, his urine was constantly dribbling away, and was caught in an old leather pouch. He had a long prepuce. The fistula in the urethra was five-eighths of an inch long, and about the same width. The entire urethra was a succession of dams and strictures. The buttocks were swollen, and doughy to the touch. He was taken to the hospital, and a week later the lateral operation for stone was performed. The stone weighed seven drachms, and was one and three-fourth inches in length, and one inch in width; it consisted of phosphates. The man made a good recovery. About a week after recovery from this operation, the doctor began to close the urethral fistula. The edges of the fistula were made raw, and brought together by means of silver sutures, and the fistula closed; but a new one was made by the wire, through which the urine flowed instead of going on to the meatus. This little fistula was cauterized, but to no purpose. The urine continued to flow through it. Finally, Dr. Stone, upon invitation, performed internal urethrotomy, without an anæsthetic. All the strictures were completely divided. Next, the operation for phymosis was successfully performed. After allowing the patient a short rest, he was taken to a dentist's office and a sound introduced into his urethra; then a drill (such as is used for boring out cavities in teeth) was pushed through the minute fistula down to the sound. Every part of the annoying little opening was thus completely denuded. To draw the edges of the fistula together, hare-lip pins were used. The patient was put in bed for a week, wearing a catheter. The same operation was performed a second time, and at last the patient was completely cured.

Dr. R. D. Barber, of Worthington, reported a case of empyema occurring in a boy of nine years of age. Twenty ounces of pus were drawn off by aspiration. It accumulated again, and was again drawn off. A drainage-tube was introduced, and the cavity of the pleura washed out with carbolized water. It was a long time before pus ceased to flow through the tube. When this took place the tube was withdrawn and the wound allowed to heal; the boy was then quite well.

Dr. C. H. Lavell, of St. Paul, reported some interesting cases. Among them was a case of a man, aged forty, on whom he operated for pterigia, removing three of these growths. The case was interesting, not only on account of the unusually large size of the growths, but because of the presence of a double growth in one eye.

Both the internal tumors impinged on the cornea. and were transplanted. The external one was slightly attached to the margin of the cornea, and was dissected off and removed. Result satisfactory.

He also reported a case of *dermoid tumor* of the sclerotic, of very large size and partially adherent to the outer edge of the cornea, and by its size interfering with the movement of the eyeball outward. The eyelids were also prevented from being properly closed. The history and pathology was given, and the tumor was removed by careful dissection from its attachment. The wound healed without causing any noticeable deformity.

The vitality of the eye was shown by a case in which he had operated for artificial pupil. On the day following the operation, the patient, a boy, was taken home by his father, in the midst of a snowstorm, a distance of fourteen miles. When he was next seen, which was not for two months, the eye was found to be in good condition; no trace of iritis, and the pupil clear.

The officers elected for the ensuing year are: *President*, Alex. J. Stone, of St. Paul; *First Vice-President*, E. J. Davis, of Mankato; *Second Vice-President*, R. S. McMurdy, of Minneapolis; *Third Vice-President*, J. Vivian; *Secretary*, C. H. Boardman.

After the appointment of the usual standing committees the Society adjourned to meet in St. Paul the third Tuesday in June, 1881.

◆

Small-Pox in Birds.—In Europe and Hindostan variola is so common in pigeons and poultry as to constitute a veritable plague. Thus Guersent records that out of a dovecote of 1,000, scarce 100 could be found that did not bear marks of the disease, while Tytler says the poultry-yards in India were habitually depopulated by the plague. Bechstein and others claim that this is the true small-pox, derived from the human being and conveyable back to man; while others, like Toggia and Gilbert, assert that it is communicable to the sheep. That this affection has not been recognized among us may be due to a difference in the environment which modifies the infection, or, perhaps, to the fact that men and pigeons do not live so much in common here as in Italy and India. Such an occurrence under Italian skies should, however, demand a careful investigation into the reality of such infection in our own States, and especially the Southern ones, during the prevalence of an epidemic of small-pox, so that whatever danger arises from this source may be detected and guarded against.—Prof. James Law in *Bulletin of National Board of Health.*

Correspondence.

PHYSICIAN AND PHARMACIST.

Counter-Prescribing—Substitution and Repetition of Prescriptions—The Dispensing Question.

To the Editor of The Medical Record.

Sir:—In your remarks on counter-prescribing and the relations between druggists and physicians, I was interested in that part which referred to the practice which some druggists have of informing their customers of the nature and contents of the prescriptions. I admit that this is often done by pharmacists, but is, perhaps, oftener done by the physicians themselves. From what I can see, it appears to be the fashion for physicians to tell their patients what medicines are prescribed. What is the result? The patients get the medicines themselves, without asking the physician. As I am one of the Othellos, I have enough of objection against being left out in the cold without any occupation, to protest against this method of doing things. Here, for instance, is a patient who has a touch of the ague. He knows that his doctor prescribed quinine for him before for the same trouble, and that knowledge serves him in good stead when he wishes to prescribe for himself. And this patient is not like the hero in the song—

> "Who gives his neighbors none,"

for he distributes his knowledge of the remedy to all his acquaintances. So it is with other fashionable remedies. Thanks to the medical profession, it is not necessary for the druggist to prescribe bromide of potassium for sick headache, or pepsin for indigestion, or cod-liver oil for phthisis, or hypodermic injections for pain. All this is demoralizing. When a patient says that he thought that he ought to take quinine, and that drug is prescribed, it is very flattering to his judgment to know that he agreed with his doctor; but there is something disagreeable, in a business sense, in paying for advice which was anticipated. Hence, we cannot blame him for regretting that he had called the doctor at all.

Let any physician, in any community not entirely in the backwoods, produce a hypodermic syringe, and ten chances to one the patient will ask if he (patient) is to have some morphine. I do not mean to say that there should be any dreadful secrecy about this business of prescribing; but this loose way of speaking of remedies before patients conveys the impression that the remedies are not of much account, can be used by any one, repeated as often as necessary, and that the science of therapeutics is nothing more than the fitting of pegs in holes already made for their reception. Even if the physician does not always enlighten the patient and satisfy his curiosity, the obliging druggist is ready to supply what would seem to be the necessary information. Allow me, sir, to protest against this practice, as injurious to both patients and physicians.

As things are going on at present, there seems to be but one way of meeting the difficulty, and that is for each physician to take his individual patients in his own hands, dispense his own medicines, and keep his own counsel.

Very respectfully yours, A Junior M.D.

To the Editor of The Medical Record.

Sir:—As a pharmacist, I would naturally incline to an exclusive prescription business, and would gladly follow out the suggestions contained in the article "Pharmacist and Physician," but such are impossibilities. We must all admit that the argument in favor of so doing is not altogether on the side of the prescriber. The pharmacist must live as well as the doctor. But the truth is, there are few, if any, pharmacists in this city who can live on a prescription business alone. The profits are not so great as they seem, and with the competition of a pharmacy on every second or third corner, said profits are fast dwindling to an insignificant figure. Aside from the latter condition of competition, which, with such significant facetiousness, is called the life of trade, we have several other drawbacks. There is the heavy rent for an inviting shop, clerk-hire for night and day work, gas-bills, etc. In order to get money to pay for this, there must be some way of making it besides trusting to a score or two of prescriptions that may or may not be brought in. The patent medicine trade is a necessity. The people will have their pain-killers, blood-purifiers, and the like, the medical profession to the contrary notwithstanding. Each of these so-called remedies as an article of trade commands a profit, and there does not seem to be any good reason why they should not be sold. The pharmacist does not recommend their use more than does the physician. I do not take up a medical journal without seeing certificates from Prof. this and Dr. that, attesting the wonderful properties of some so-called new preparation, how it surpasses everything else for the treatment of particular diseases, etc., etc. Pharmacists do not go quite so far as that when they simply sell the articles. Physicians really create a demand for many of the articles for the sale of which we are sometimes blamed by the medical profession. The latter may not go so far as to give a certificate for baby soothing-syrups and other like nostrums, but some of the leading lights stop very little short of so doing. I have in my prescription-books, prescriptions ordering not only proprietary but really patent medicines, and that by men who occupy leading positions among their brethren. I ask, is it more harmful to supply a demand for these articles than it is to create the demand?

To go back to the living by a purely prescriptive business, there is another good reason why it is becoming less and less profitable. Especially is this so compared with twenty-five or thirty years ago. Physicians do not prescribe as much medicine as they did formerly, nor does it seem to them to be necessary to use a number of different ingredients in one recipe. And when a number of ingredients are wanted, the accommodating wholesale manufacturer comes in to meet the demand, and is ready to supply the physician with pills to order by the thousand at the nominal rate of machine labor, with the formula and dose on each bottle. The same is the case with single remedies, to which the physician of the present day is peculiarly inclined.

I find also that physicians, as a class, are not given to help the druggists as they should. I do not pretend to prescribe for a physician, because I know it is unfair to physician and to patient; but the physician thinks he does ordinary justice to his patient when he tells the latter that he can add so much water to the salt, or buy the powder in quantity and divide it into so many parts, so that the pharmacist may not make a living. As I said before, and as you freely admitted in your editorial remarks, there are two sides to this question.

Very truly yours,
B. A. C.

New York, August 8, 1880.

To the Editor of The Medical Record.

Sir: — Your remarks in the last two numbers, on the relations between druggist and physician, were so well taken that I am tempted to endorse that part of them referring to comments on prescriptions, by reference to my own experience.

Not long ago I prescribed some Hoffman's anodyne for a nervous old lady, and indicated the dose at the end, with the usual "Use as directed." The next morning my lady drove to my office and in great consternation asked if that was not very strong medicine that I had ordered her. I assured her to the contrary, when she told me that her gravest suspicions were aroused by the druggist (a reputable one on Broadway) asking her coachman if the medicine was for the horses! Naturally she associated horse medicine with some extra strength. The coachman could not give any more direct answer than that Madame was sick, and the medicine was fixed up. When she showed it to me it looked as if the druggist thought it was intended for the horses, as it was murky from the addition of water, and was anything but an inviting preparation. I was compelled to send her to a pharmacy in which clerks are employed who do not ask useless and senseless questions, and I also take care that none other of my patients have their medicines put up by the compounder of horse medicines. If I were to publish the name of the man who keeps the cattle establishment it would cause half the prescribers on Murray Hill to open wide their eyes in wonder; but, for the credit of a leading member of the College of Pharmacy, I abstain. Similar instances of indiscretion must have occurred to others.

I have frequently been the victim of another species of officiousness on the part of the apothecary. I had a lady once who had a whimsical notion that quinine entered her bones and that she could not take it without "harm to her constitution."

It so happened that there was such a strong malarial element about her case that quinine in full doses was called for. I did my best to leave the question of quinine an open one, assuring her that the medicine would not harm her, etc. What was my astonishment to be the victim of a scene in my office by being charged with misrepresentation in trifling with a delicate woman's constitution, etc., all because the officious simpleton who made up the prescription volunteered the statement that there was not only quinine in the mixture, but very full doses too. This was not in the horse medicine shop, but it was in an establishment equally pretentious and high-priced.

* * *, M.D.

New York, August 10, 1880.

To the Editor of The Medical Record.

Sir:—I have read with much pleasure the admirable articles "Physician and Druggist," and although I cannot agree with you in some particulars as to the best way to mend matters, I am certainly convinced that the advice given is generally correct. I am, perhaps, a little too radical in my methods of action; but I believe with the old Scotchman "that honesty is the best policy, because I have tried *baith*." I mean honesty to one's self. In former days, when full of ambition to get into practice, I associated myself with a drug store, that is, for the sake of writing all the prescriptions for the store, I was allowed to have my sign displayed there and to have office hours. I soon found, however, that the apothecary made a great deal more money than I did; but, as I was getting into a business, I did not mind it much. Finally, I became so situated that I had an office of my own and many of my patients would get their prescriptions filled at the old place. I could not object to this, inasmuch as everything seemed to be done in a business-like way.

Soon, for a very good reason that my actual practice did not warrant it—but which was not so understood by my former employer (?)—there did not go so many prescriptions from me to the "old stand;" consequently, to keep the proper end up the proprietor began to prescribe himself, and, as he could do it much cheaper than I could, it was not difficult to see who could be the fittest in the survival. A generous rivalry sprang up between us to benefit the public, and the end of it was I moved away. Not because I did not want to benefit the people; but because I could not love my neighbor druggist as myself. I was well aware that a "rolling stone" was not likely to "gather moss;" but the grade was the wrong way with me and I yielded to the inevitable. I may say that those were the days when polypharmacy showed skill and before steam-engines mixed pills.

When I obtained my new office I turned over a new leaf. I cultivated merely a nodding acquaintance with the pharmacists in the neighborhood and dispensed my own remedies. I do not make any profit out of my medical stores; in fact, I am willing to throw them in with the advice, preferring to lose my medicines rather than my patients. And then, I am not annoyed by having my prescriptions repeated and repeated without my consent. Many of my youthful prescriptions are going the rounds to this day; but I am not now accountable—to use a rather strong figure, perhaps—for unchaining the tiger; my only concern is that the poor compounder will in the end have more to answer for than he dreams of.

I do not mean to say that all the medicines I prescribe are dispensed by me, but the larger majority are. It would surprise most physicians who have not given attention to the subject to know how well and how satisfactorily the plan works. Not only is there an opportunity for giving the particular preparation you desire them to take, but generally in a very convenient and pleasant form and with virtually no expense to the patient. Again, if it is necessary to administer a placebo, it is a matter entirely between physician and patient.

All this takes time, it is true; but no more time than is usually spent in one's office in general outside converation with the patient or in making an extra entry in your note-book.

I am, with great respect,
S.

THE TWO KINDS OF VIVISECTION—SENTISECTION AND CALLISECTION.

To the Editor of The Medical Record.

Sir:—Is it not time for the distinct verbal recognition of the difference between painful and painless experimentation upon animals?

All well-informed persons are aware that the vast majority of vivisections, in this country at least, are performed under the influence of anæsthetics; but the enthusiastic zoölaters, who desire to abolish the objective method of teaching physiology practically, ignore this fact and dwell chiefly upon the comparatively infrequent operations which are attended with pain.

Having read the arguments upon both sides and had some correspondence with leaders of the anti-vivisection movement, I have been led to think that the discussion may be simplified and a right conclusion sooner reached, if we adopt new terms corresponding to the two kinds of experimentation.

To use words with no warrant of ideas may be foolish, but it is not necessarily a mark of wisdom to refrain from the employment of terms which have a real significance.

Let us consider an analogous case: aside from color and size, the *cat* and the *leopard* are almost identical, and are commonly regarded as two species of one genus. Suppose a community to be unacquainted with the cat, but to have suffered from the depredations of the leopard, which they call *felis*. Now, suppose some domestic cats to be introduced and to multiply as is their wont. In the first place, for a time at least, it is probable that the same name, *felis*, would be applied to the smaller animal, with perhaps a qualifying word. In the second place, should there be certain persons, both devoid of interest in the cats and filled with pity for the mice devoured by them, is it not likely that they would endeavor to include the cats under any ban which might be pronounced against the leopards? Would they not be apt to succeed, especially with the more ignorant and impressionable members of the community, so long as they could assert without contradiction that the "mouse-eater" was only a *felis* upon a smaller scale? Would not even the reputation of the leopards suffer by reason of the multitude of the cats thus associated with them? In short, would full justice be done to either animal until the practical differences between them should be admitted to outweigh their likeness of form and structure, and be recognized by the use of distinctive names?

In like manner there are those who ignorantly or wilfully persuade themselves and others that all experiments upon animals are painful because some of them are now, and most of them were in former times; also, that painful experiments are common because vivisection in some form is generally practised. It is all *vivisection*, and as such it is "cruel, revolting, or brutalizing."

Having waited long in the hope that some candid discussion of the whole subject might contain the needed terms, I venture to suggest that painful vivisection be known as *sentisection*, and painless vivisection as *callisection*. The etymology of the former word is obvious; the distinctive element of the latter is the Latin *callus*, which, in a derived sense, may denote a state unknown, strictly speaking, to the ancients.

Some idea of the relative numbers of callisectionists and sentisectionists may be gained from the fact that I have been teaching physiology in a university for twelve years, and for half that time in a medical school; yet I have never performed a sentisection, unless under that head should be included the drowning of cats, and the application of water at the temperature of 60° C. (140° F.), with the view to ascertain whether such treatment would be likely to succeed with human beings.

I think that even elementary physiological instruction is incomplete without callisection, but that sentisection should be the unwelcome prerogative of the very few whose natural and acquired powers of body and mind qualify them above others to determine what experiments should be done, to perform them properly, and to wisely interpret the results. Such men, deserving alike of the highest honor and the deepest pity, should exercise their solemn office not only unrestrained by law, but upheld by the general sentiment of the profession and the public.

OLEUM TEREBINTHINÆ IN CANCER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Several items have appeared of late in regard to the use of oleum terebinthinæ and other turpentines in cases of cancer. In two cases that have lately come under my observation I have used the oil of turpentine pretty thoroughly, and while deriving no more general effect from it than from any other remedy in the disease, its ameliorating effects over certain features are such as to make it worth recording.

In a case of scirrhous breast, which was not removed, a poultice was applied, over which was poured ol. terebinth.; it was also given internally. The incipient ulceration was checked, and the disagreeable odor of cancerous ulceration entirely obviated. From this I was induced to try it in a case where extensive ulceration had taken place in the tumor, recurring after the breast had been removed. Salicylic and benzoic acids had been used without effect. Turpentine was applied freely, which at once arrested the ulceration and destroyed all fetor. In both cases death resulted from the extension of the disease to other organs; but one unpleasant feature was removed.

In a case of cancer of the uterus, now under observation, tar-water was used as an injection, which seems also to act as a disinfectant, but not so effectually as a turpentine emulsion which is now being applied.

Yours truly,
P. J. FARNSWORTH, M.D.
CLINTON, IOWA, July 20, 1880.

◆

THERAPEUTIC EFFECTS OF MODERATE ALTITUDES IN PULMONARY CONSUMPTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the management of phthisical cases of whatever variety, the most important factor is to be looked for in climate.

The therapeutic value of high altitudes, though as yet not universally acknowledged, is forcing itself upon the attention of the profession. Still, the opinions of specialists are widely divergent upon this point. The mild southern climates, the sea-shore, life on islands, the cold and comparatively dry climate of Northern States—like Minnesota—all have their advocates and their statistics. There are authorities also who claim for *medium* altitudes, irrespective of proximity to the ocean or the degree of latitude in which a locality is found, the same therapeutic value in the management of consumption as that of high altitudes.

It will be my endeavor to show some of the fallacies of this faith, more especially as regards low or medium altitudes.

Success in the treatment of pulmonary phthisis is claimed for such mountain regions as the Orange range in New Jersey, the Ramapo valley, the Adirondacks, a spur of the Cumberland mountains in Tennessee, and others of limited altitude. Last year I was interested in reading Dr. Loomis's paper upon the "Therapeutical Value of the Adirondack Region in Cases of Pulmonary Phthisis." Since the above-named region is a fair representative of lesser altitudes and their effects upon chronic pulmonary processes, it will serve as an illustration of facts equally applicable to all. What I wish to demonstrate is that *symptoms* only are benefited, and then only after a very protracted residence, while the physical condition remains almost unchanged.

In enumerating the advantages of the Adirondack region, the amount of rain-fall is claimed to be of little importance, provided the external configuration of the soil is satisfactory. This is as true as it is important. Unfortunately, however, this only holds good where we have the presence of a sandy, porous soil and a moderate amount of rain-fall. Meteorology teaches us that "the total evaporation from the earth's surface in a year must be *equal* to the total precipitation in the form of rain, snow, dew, etc."

In the Adirondack region we have, in addition to the rain- and snow-fall, the presence of numerous lakes of various dimensions, and, what is of greater moment, sufficiently close proximity to the Atlantic ocean for that region to be affected by its moist currents. The above-quoted article goes on to say that "the peculiar *dampness* which acts most unfavorably is not usually present in those localities where there is the gratest rain-fall, nor is it present because large bodies of water are in close proximity."

Now, the same conditions which cause a rapid evaporation from the earth's crust also tend to a somewhat lesser evaporation from the surface of lakes and creeks.

It is admitted that the Adirondack region has a moist, cool climate; that the rain-fall is above the average for other parts of the State, and about fifty-five inches; that there is considerable rain until about the middle of June; that in summer nights heavy dews fall; that during the winter there is a preponderance of cloudy days and snow-storms, the sky being constantly overcast, and there is no preponderance of clear days at any season. I agree with Dr. Loomis and others that *pure* air is necessary to diseased lungs. But that it does not matter whether that pure air is hot or cold, damp or dry, is going too far. The accepted theory is that of Dr. C. T. Williams, of England, to the effect that, taking collectively all forms and degrees of phthisis, dry climates are most likely to arrest the disease.

Is pure air to be found in regions such as are described above? To insure the presence of unadulterated pure air we require the most unobstructed effects of the sun's rays—above all, unobstructed sunlight. These effects are to be met with only at high altitudes free from the moist ocean currents. Here alone do we find perfect freedom from dust, vapors, or noxious gases, representing, in their turn, solids, fluids, and gases.

Turning our attention to the results attained in regions of limited altitude, such as the Adirondacks, we may be permitted to take Dr. Loomis's report of twenty cases as a fair type of what is actually accomplished by prolonged residence in such regions.

It would lead us too far to analyze individual cases as reported from various localities by different authors, the results being essentially in accordance with those reported by Dr. Loomis.

Of twenty cases ten recovered, six were improved, two were not benefited, and two died. Not an extraordinary percentage of deaths. But, when we come to the "recovered" and "improved," a careful perusal of these cases will establish the following facts:

1. Two only lost their slight catarrhal infiltration, which in both cases is reported to have been too limited to produce any appreciable dulness on percussion.

2. In all cases (with the exception of the above two) their recovery or improvement is based upon *gain in weight* and *loss of cough.* In the few cases where a physical examination of the patient is noted down as having been made after his stay in the Adirondacks, the important admission is made that active symptoms remained. "Localized bronchial râles," "well-marked pleuritic creakings," are signs of conditions not only likely to cause successive inflammatory conditions, but are progressively active signs themselves.

3. The length of time required for patients to lose their most active symptom, viz., cough, thereby proving the absence or reduction of muco-purulent secretion, is a point for consideration. In order to reduce the amount of secretion from the mucous membrane of the respiratory tract, whereby we get rid of fever and night-sweats, and to gain a few pounds in weight appears to have taken all the way from two to eleven years.

The legitimate conclusions to be drawn from the above facts, in connection with other details in the above twenty cases, are as follows:

1. As regards *gain in weight.* Dr. Brehmer, of the Goerbersdorf Sanitarium, has observed and proven that gain in weight bears no relation whatever to the actual condition of the lung. I have long been convinced that a mere gain in adipose tissue (for this is what gain in weight amounts to) is a hinderance to the absorption of an infiltration, and *vice versa.*

2. *Loss of cough and expectoration* is never absolute and total where any infiltration remains. The lessening of the quantity of sputa and of the paroxysms of coughing diminishes, for the time being, chronic septicæmia, to which is due the fever.

3. But loss of cough, diminution of expectoration, and especially the much lauded gain in weight, may be attained by any change of climate different from the one the patient resides in. Yes, more than that. It is immaterial whether the patient changes from city or country to sea-shore, or *vice versa,* from the Atlantic coast to the Mississippi valley, north or south, as it is whether the change be from a cold to a warm climate, or from the level of the sea to moderate altitudes. The same amelioration of symptoms may be accomplished by residence in Florida, in the Carolinas, in the eastern part of Tennessee, in Texas, in Minnesota, in the Adirondacks, or upon the islands of the Pacific coast or West Indies.

Any more or less radical change will be followed by an amelioration of symptoms, accompanied by an increase in adipose tissue, while the physical signs will remain almost undisturbed.

4. This much being allowed for moderate altitudes, and according strictly with the results of the cases quoted above, it is evident that it requires higher altitudes to bring about absorption and cicatrization of pulmonary infiltrations. The proper altitude is the one at and above which consumption is not met with. It varies with latitude, and, in accordance with the shape of our globe, is found to increase as we approach the equator from the north or south.

J. Hilyard Tyndale, M.D.

Manitou, Col.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 7, 1880, *to August* 14, 1880.

Havard, V., Capt. and Asst. Surgeon. To proceed to Ft. Clark, Tex., and report to the Comd'g officer 1st Inf'y, for duty with his command. S. O. 158, Dept. of Texas, August 8, 1880.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending August 14, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Aug. 7, 1880.	0	15	20	1	11	30	0	0
Aug. 14, 1880.	0	6	22	4	6	36	0	0

Cruelty to Shop Women.—In concluding an editorial upon the cruelty exercised by shopkeepers in keeping shop-girls so many hours on their feet, the *Lancet* says of the ladies who go shopping: "We fear the number of feeling women is small. If ever there was a proof that the feminine nature is *not* gentle, or the sympathies of woman keen and active, the perpetuation of this grievous wrong is a proof that cannot be gainsaid. To obtain a wider selection of materials for a dress, or see the newest patterns of robe or mantle, a 'lady' will sanction by her patronage and aggravate by her exacting demands on the strength and endurance of those who wait upon her, the 'cruelty to women' we are striving to put down."

Carbolic Acid Powder.—The formula for the carbolic acid powder in use at the Mt. Sinai Hospital is:

℞	Acid carbolic, parts..........	25
	Rosin, "	60
	Stearin....................	15

M.—Add plaster-of-Paris, parts, 700.

In a former issue, the proportion of stearin given was .15 parts.

The Oil of Fennel is the last thing offered as a deodorizer of iodoform. Twenty minims of the oil are to be added to a drachm of the iodoform.

The Conference on Vital Statistics.—In a supplement to the *Bulletin of the National Board of Health* for July 3d, the proceedings of this Conference, held in Washington May 6th, are given in full. Twenty-four delegates were present, one-half of them being from New York and New England. The topics discussed were: The Standard Nomenclature; The Basis of complete Individual Records as Statistical Hints; How to Secure Numerical Completeness; The Periodical Summaries, Statistical Abstracts, Bulletins and Reports; Methods of Revision and Perfecting Individual Records.

In regard to the standard nomenclature, the following resolution was passed:

First. That the nomenclature published by the Royal College of Physicians of London be provision-ally adopted, with the understanding that in so far as names of diseases or pathological conditions are not contained therein each one shall be at liberty to use such name as he deems best.

Second. That a committee of five be appointed by the Chair whose duty it shall be to indicate the most urgently needed additions to said nomenclature at the present time, and that this committee shall be instructed to confer with the committee of the Royal College of Physicians in charge of the revision of said nomenclature with reference to obtaining a uniform system, both for Great Britain and her colonies, and in this country.

It was also voted that this committee bring the matter to the attention of the American Medical Association, and communicate with the different registrars, State and municipal, throughout the country upon the subject, requesting them to join in the adoption of this nomenclature in accordance with the resolutions passed.

As supplementing the above action, another resolution was passed as follows:

"*Resolved*, That for purposes of classification the general diseases be grouped together as proposed in the nomenclature just adopted, and that local diseases be arranged alphabetically by systems and organs."

In regard to the question of paying physicians for returning vital statistics, the Conference did not think it wise to commit itself, although admitting in general that such a measure would be just.

The committee on the minimum amount of information that should be required in reports of deaths, gave the following as the necessary items:

1. Date of death. 2. Name of the deceased. 3. Age, in years, months, and days. 4. Particular location of death. 5. Sex. 6. Color, and with color the race, as Indian, Mongolian, etc. 7. Whether married, single, or widowed (divorced). 8. Occupation. 9. Birthplace of deceased. 10. Birthplace of parents of the deceased. 11. Place of burial. And in addition to the above the cause or causes of death to be given particularly, as follows: Remote, immediate, and concurring causes.

The Conference discussed the other questions presented to them, passed resolutions, and drew up forms for the better securing of vital statistics. The adjournment was *sine die*.

Anæsthesia by Rapid Respiration.—Dr. Benjamin Lee relates in the *Phila. Med. Times* several cases in which an analgesic effect was produced by rapid and forcible respiration. It is a method that has been employed successfully for some time by Dr. Bonwill, a dentist of Philadelphia (*vide* p. 211). Dr. Lee's cases were those in which abscesses were opened or teeth extracted. Analgesia was not produced in every case, but it was brought about often enough to show that the effect is a genuine one. The respirations have to be kept up for a minute or more.

Skin-grafting.—A number of cases of skin-grafting have recently been circulated through the medical journals, and surgeons seem to be vying with each other to see who can report the most remarkable one. The last is that of a young woman who has been a patient in St. Luke's Hospital and whose history has already been published in The Medical Record. In 1874, while working in a factory, the girl had her scalp torn from the calvarium. Not long after she came to St. Luke's Hospital, in which institution she has been most of the time ever since. The wounded surface, which had begun to cicatrize, was stimulated so as to secure good granulations. Grafts were then applied. In the ensuing four years, 14,000 grafts are said to have been placed on the wound. Only a small proportion kept their vitality, but these have been enough, at last, to furnish a skin for the once denuded cranium.

American Pharmaceutical Association.—The twenty-eighth annual meeting of this association will be held at Saratoga, New York, Tuesday, September 14, 1880.

An International Congress of Charity Commissioners will be held in Milan, Italy, from August 29th to September 4th, next. Invitations have been sent out to all the principal cities of the several nations of the earth, asking them to send representatives.

The Twenty-eighth Annual Meeting of the Maine Medical Association was held at Portland, June 15th, 16th, and 17th, and seems to have been a very successful affair. In the inaugural address of the President, Dr. S. C. Gordon, the present law in regard to dissection was discussed, and its injustice to medical science shown. As it now stands, the physicians of Maine can get material for dissection from only two sources: a person may will his body to the dissecting-room, and the bodies of persons dying in penal institutions can be had for dissection, provided the criminal has not made a request for internment. Practically nothing comes in from either of these sources, and the physician who wishes material for dissection must either break the law himself in order to get it, or must hire some one else to do it for him.

Acting upon the suggestion of the President, the Society appointed a committee to try and secure legislation upon the matter.

The annual oration of Dr. O. A. Horr treated of the progress of medicine in the State, and dwelt especially upon the need of a board of health. This is not likely to be obtained at present.

About a dozen papers were read, most of them being of scarcely average merit.

The officers for the ensuing year are as follows: President, Dr. W. W. Greene; Secretary, Dr. C. O. Hunt; Treasurer, Dr. A. S. Thayer—all of Portland. The society adjourned to the third Tuesday in June.

The International Medical Congress.—The committee having this matter in charge have nearly perfected their arrangements. Sir James Paget has been nominated President of the Congress. There will be fifteen sections, of which the chairmen are: Physiology, Prof. Michael Foster; Anatomy, Prof. Flower: Pathology, Dr. S. Wilks; Medicine, Sir Wm. Gull; Surgery, John Eric Erichsen; Obstetrics, Dr. McClintock; Pediatrics, Dr. West; Mental Diseases, Dr. Lockhart Robinson; Ophthalmology, Mr. Wm. Bowman; Otology, Mr. W. B. Dalby; Dermatology, Mr. Erasmus Wilson; Diseases of the Teeth, Mr. Edwin Saunders; State Medicine, John Simon; Military Medicine and Surgery, Surgeon-General Longmore; Materia Medica and Pharmacology, Prof. T. R. Fraser.

The General Medical Council and Preliminary Education.—The General Medical Council of Great Britain, which has charge of the medical affairs of that nation, began its annual session in London, July 7th, Dr. Acland, its president, being in the chair. Most of the time during its first few days of meeting was devoted to the subject of preliminary education. An elevation in the standard of the preliminary examinations was thought to be much needed. The following schedule was finally adopted as representing the minimum requisite for matriculation in a medical school.

1. English Language, including Grammar and Composition; 2. English History; 3. Modern Geography; 4. Latin, including translation from the original, and Grammar; 5. Elements of Mechanics, comprising: (*a*), Arithmetic, including vulgar and decimal fractions; (*b*), Algebra, including simple equations; (*c*), Geometry, including the first two books of Euclid; 6. Elementary Mechanics of Solids and Fluids (this subject can be passed either as a preliminary or at the first annual examination); 7. One of the following optional subjects: (*a*), Greek; (*b*), French; (*c*), German; (*d*), Italian; (*e*), any other modern language; (*f*), Logic; (*g*), Botany; (*h*), Elementary Chemistry.

A motion was also agreed to: "That it is desirable that intending candidates for the medical profession should, before they enter upon the purely medical curriculum, have been instructed in the rudiments of Natural Science, physical, chemical, and biological."

The Council also discussed the subjects of ophthalmological and obstetric instruction, and recommended that these branches form part of the regular curriculum.

DEATH OF DR. LUCAS V. NEWTON.—We regret to announce the death, on July 10th, of Dr. L. V. Newton, editor of *The Druggists' Circular and Chemical Gazette.* Dr. Newton was born in 1809, at Griggstown, N. J. He spent his early life in journalistic pursuits, not graduating in medicine until he was twenty-six. Dr. Newton led for a time a somewhat roving life, practising medicine in Philadelphia, London, Virginia, in New Orleans during the yellow fever plague of 1848, and finally coming to New York. In 1858 he became editor of *The Druggists' Circular*, then having but a small circulation. By his literary and scientific accomplishments and his business capacity he made his paper one of the best pharmaceutical journals in the country. It remains as the best monument of an able and widely esteemed man.

AORTIC COMPRESSION BY THE RECTUM was performed successfully by Mr. Richard Davy a short time ago. The aorta was compressed for four minutes and pulsation stopped in the femorals. The rectum sustained no damage. The operation performed during the compression was a uterine one.

THE TEMPERATURE OF THE BREATH.—A good deal of curiosity is being expressed in regard to the apparently high temperature of the breath, under certain conditions. If we take an ordinary clinical thermometer, wrap it up pretty tightly in several folds of a silk handkerchief, apply it closely to the lips and breathe gently through the silk just over the bulb of the thermometer for about five minutes, always making the inspirations through the nose, we shall find that the thermometer will show a temperature ranging from 101° to 108°, or even 109.5°. Dr. E. S. Clark first called attention to this phenomena in the *Medical Herald.* The facts are corroborated by Dr. Dudgeon in the *Medical Press and Circular.*

PROFESSOR HUMPHREY ON THE EVOLUTION OF MAN.—In Prof. Humphrey's Rede lecture on Man, delivered a short time ago at the University of Cambridge, he pleaded for long and patient investigation, especially in coming to the discovery or comprehension of any process, whether of natural selection or any other, by which the large cranial cavity of man can have been evolved in early men. He gave full weight to the argument for the size of the brain at birth, and the perfection of the lungs at the same period. At any rate, the brain of primitive man appeared to have been structurally fitted for higher duties than they were ever called upon to perform. His brain was prophetic of his future. Ability is to be measured by the power to deal with the material before us, and thus it is doubtful whether the ability of the present was greater than that of preceding generations. Progress did not necessarily imply improvement, and increased means did not imply greater power to be wielded with better effect. The physical capability he thought long preceded functional activity, and man's advance to civilization was the result of the response of his nature to his conditions.

THE NEW YORK STATE BOARD OF HEALTH has made out its forms for the registration of marriages, births, deaths, transit of bodies. These have been forwarded to the boards of supervisors, clerks of towns, villages and school districts, and local health boards in the State, with directions for their use.

The next regular quarterly meeting of the Board will take place in New York city, August 18th.

THE NATIONAL MEDICAL LIBRARY, a work which has been in course of preparation nearly twelve years, is now in the hands of the printer, and is expected to be ready for issue in two or three weeks. The second volume will follow without delay. The completed work will make about ten volumes, royal octavo, of 1,000 pages each, and notice is given that only a limited number of copies will be available for distribution, probably not more than enough to supply the various public libraries and those persons who have been large contributors to the library. The public printer will, however, supply all who may order in advance and remit the cost of publication, estimated at $2.50 a volume, with 10 per cent. added, according to law.

The work is much more than its title indicates, being, in fact, a key to medical literature everywhere, arranged for convenient reference both to subjects and authors. It will thus become an index to every physician who owns a library, as well as to the medical portion of the public libraries in his neighborhood.

The National Medical Library now contains more than 50,000 bound volumes and 60,000 pamphlets, with complete files, for a long series of years, of nearly all the medical periodical publications in the world. Plans have been drawn for a new library building to be made of brick, and to cost $250,000, and the matter will be urged upon the attention of Congress at its next session, and an effort made to secure an appropriation for the preliminary work upon the new building.

FOR THE REMOVAL OF TAN AND FRECKLES, Dr. J. Nevins Hyde endorses the formula of Prof. White.

℞.	Hydrarg bichlorid..............	gr. vj.
	Acid. muriat. dil................	ʒ j.
	Aq..............................	℥ iv.
	Alcohol,	
	Aq. rosæ.....................āā	℥ ij.
	Glycerine......................	℥ j.

M. Apply at night, and wash off the skin with soap in the morning.

Growth of Human Hair and Skin.—Professor Moleschott has found that the average daily growth of the human hair amounts to .20 gramme (gr. iijss.). The loss of nitrogen in this way amounts to .0287 gramme (gr. ss.) daily. The hair grows faster between the ages of 18 and 26, when the amount is as given above. Between the ages of 32 and 45 the daily quantity is .14 grammes, or about one-third less. More hair is produced in summer than winter. Frequent cutting increases the rapidity of its growth.

Concerning the growth of nails, it was found that 1.825 grammes (ʒ ss.) were produced in a year in one case. The growth was more rapid in summer. Assuming that the whole epidermic surface measures 1,614 sq. metres, Prof. Moleschott estimates that there is a daily loss of 14.35 grammes (ʒ iijss.) of epidermis through unobserved desquamation.

Twelve Thousand Dentists find employment in the United States. They drive half a ton of gold annually into dental cavities.

The Alleged Deterioration of Humanized Vaccine Lymph.—In regard to this point, which has of late been much discussed, Dr. Henry Stevens, of the Local Government Board, England, who has probably vaccinated more children than any man living, says that he has found no ground whatever for the suspicion that humanized lymph has lost its true and original Jennerian character. Dr. Atlee, of Lancaster, Pa., says that, in an experience of sixty-four years, he has seen no evidence of change or loss of power.

Juvenile Smokers.—An English physician examined 38 boys, between the ages of 9 and 15, who were in the habit of smoking. Of these, 22 suffered from various disorders of circulation and digestion, palpitation of the heart, and more or less marked taste for drink.

Model Nursery.—The municipal authorities of Paris have decided to establish a model nursery in that city in connection with the children's hospital, to experiment with artificial nourishment. The direction of the institution is given to Professor Parrot.

Tea.—This was sold for £6 or even £10 per pound weight until the year 1657, up to which time it had only been used in England as a *regalia* in high treats and entertainments, or as a present to princes and grandees. But in the above year Thomas Garway first publicly sold tea in the leaf, and "a drink made according to the directions of the most knowing merchants and travellers in eastern countries." Many noblemen, physicans, merchants, and gentlemen, resorted to his place in Exchange Alley, near the Royal Exchange "to drink the drink thereof."

In 1658 tea was widely advertised thus for sale, as: "That excellent, and by all physicians approved *China drink*, called by the Chineans Tcha, by other nations, tay or tee, is sold at the Sultana's Head, Coffee House, by the Exchange, London."

There was no tax then on tea or coffee when imported, but made up into a drink it was charged with a tax of 8 pence a gallon.

The drink called *cophee*, was also advertised in 1657 to be sold in the morning and at three o'clock in the afternoon, in Bartholomew Lane.

Tea with milk has been called the "fragrant lymph."

Cibber says: "Tea! thou soft, thou sober, sage and venerable liquid; thou female tongue-running, smile-compelling, heart-opening, wink-tipping cordial, to whose glorious cheering I owe the happiest moments of my life.

"The Muse's friend, tea, does our fancy aid,
Repressing vapors which the head invade."

Bishop Burnet drank sixteen cups every morning. Dr. Johnson avowed himself a hardened and shameless tea-drinker, who diluted his meals with tea, amused his evenings with tea, solaced his midnight with tea, and welcomed the morning with tea, and of whom it has been said: "*Tea veniente die, tea decendente bibebat.*"

Indeed, the doctor, who loved a ponderous joke, once said to a lady who accused him of drinking too much tea: "*Nec cum* TE *nec sine* TE, *vivere possum.*"

Bryan loved his tea with rum, according to the advice of Mrs. Gamp to "combine the milder infusion with the benignant influence of distilled waters."

Pepys drank his first cup of tea, "a China drink," as he calls it, Sept. 25, 1660, and his second in 1667, when on coming home, he found his wife making tea, "a drink which Mr. Pelling uses."

Dr. Johnson's tea-pot held more than three quarts. His tea-kettle had no time to cool, for with tea he solaced the midnight hour, and with tea welcomed the morn.

Mrs. Elizabeth Carter was such a diligent collector of tea pots that she left over 300, each of which possessed some traditionary interest.

Sugar.—Sugar-cane had been grown in Sicily from the year 1148; it was imported into Madeira in 1419. About the year 1503 the art of refining it was discovered by a Venetian, before which time the juice was used as it came from the cane. In 1526 it was imported from Spain by Bristol merchants. In 1553 a sugar-loaf weighing 7 lbs. was considered a beautiful present.

Coca as a Remedy for the Opium Habit, suggested by Dr. Palmer, in the *Louisville Medical News*, has received an endorsement from Dr. J. G. Core, who has used it with good results in a very old and obstinate case.

The Death-Rate from Cancer has increased at the rate of four hundred per cent. in London, England, and in Philadelphia, during the last sixty-five years.

A
NEW ASPECT OF FACIAL PARALYSIS.

By THOMAS W. POOLE, M.D.,
LINDSAY (ONT.), CANADA.

The following considerations are designed to show that the effects of paralysis of the facial nerve, on the muscles of the face, are of a different character from what they are reputed to be; and that here, as elsewhere, there is no exception to the doctrine that the true functions of nerve-force is to restrain, or inhibit, the property of contractility in muscle.

It is a curious fact that, "owing to the great size of the velum pendulum palati, a horse is unable to breathe through his mouth" (Strangeway's "Vet. Anat." p. 209). As a consequence, respiration is carried on in this animal through the nose; and when both his facial nerves are cut or paralyzed, "the nostrils immediately collapse, and the animal dies by suffocation" (Bernard, quoted by Dr. Dalton, "Phys.," p. 458).

Sir Thomas Watson, in detailing the effects of paralysis of the right facial nerve in the housemaid, Jane Smith, says: "When she tried to snuff in air through her nose, not being able to keep the right nostril stiff and open, its sides came together, and no air passed up on that side" (see p. 366). From this it is evident that were the cavity of the nose the only channel of respiration, and were the nerves of both sides paralyzed, death from suffocation would be imminent in the human subject as well as in the horse.

Now, it is perhaps needless to say that paralysis of a motor nerve displays its results solely in muscular tissue. Neither mucous membrane, cartilage, nor fibrous tissue possesses contractile power in response to nerve-action. We are therefore necessitated to seek in some condition of the nasal muscles for the cause of the sinking in of the nostrils, on which the suffocation depends. If there were muscles within the nasal cavity which became greatly relaxed or flaccid when paralyzed, it might be supposed that the swelling out of the body of these might stop up the nasal tube, and in this way cause arrest of breathing. But there are no such muscles lining the nasal cavity; and besides, the obstruction does not come by a filling up of the nose within, but by "its sides coming together," as stated by Dr. Watson.

All the nasal muscles are external to the cartilages, are subcutaneous, and amenable to direct observation. So far as appearances indicate, these muscles are by no means in a flabby or even relaxed state. On the contrary, they give evidence of having an increase rather than a diminution of their normal tone. Dr. W. A. Hammond, writing of facial paralysis, says: "Among other symptoms, it is noticed that the ala nasi is depressed, and does not expand as air is drawn in through the nostril" ("Dis. Nerv. Syst.," p. 724). Something very similar to this occurs also in the general paralysis (including that of the facial nerve) as death approaches, and in death itself, in which obvious contraction of these muscles gives to the features that "pinched" or "sharpened" aspect known as the Hippocratic face, in which contraction of the compressor nasi presses the nostril downward and inward, leaving the nasal ridge more bare and prominent. Dr. Erasmus Wilson alludes to this "compressed state of the nares . . . . in the last moments of life, or in compression of the brain" ("Anat.," p. 179); but he adheres to the popular error of attributing this condition to "paralysis of the muscles," which cannot press in the nostril if they are mere flaccid fibres. To effect this requires that the compressor muscles shall overpower the influence of the dilators, an act which requires a certain degree of contractile power, and it is needless to say that this is not to be expected if the muscles are "paralyzed." It is true that, according to our anatomical text-books, the dilators of the nose are in greater number than the compressors; and even the compressor naris muscle is set down as being a dilator. It is probable that there is some mistake here, and that, owing to the insignificance of these muscles, their actual *rôle* has been imperfectly or erroneously interpreted. From some limited personal observations I find that I can compress my own nose by a voluntary act much more forcibly than I can dilate it.

To say that the ala of the nose falls in because the muscles whose function it is to dilate it are paralysed, is absurd, because the nasal cartilages are constructed and adapted for maintaining the nostrils open. In the condition under discussion there is no superincumbent weight to press them together, and it is certain if they were let alone, and not acted upon by any influence exterior to themselves, they would continue to remain apart. A merely passive condition of the muscles outside the cartilages will not account for the nostrils being thus pressed downward and together; and hence we are forced to conclude that, as in other cases where muscles are undergoing a deprivation of nerve-influence, their property of contractility is called into play, and the muscular fibres undergo a greater or less degree of contraction in proportion to their power. For it must be remembered that this "compressed state of the naris" is not a mere casual or accidental circumstance, but is to be regularly looked for, as "among the symptoms" of facial paralysis (Hammond, p. 724).

There is nothing at all absurd or incongruous in thus asserting the contracted state of the nasal muscles during nerve-paralysis; for has not Dr. C. B. Radcliffe, F.R.S., laid it down as one of his propositions, that "there is reason to believe that ordinary muscular contraction is associated with deprivation of nervous influence, and not with a contrary state of things"? Nay, further: "that the power of muscular contraction is inversely related to the amount of nervous influence supplied to the muscles from the great nervous centres"? (see pp. 95, 100). These propositions are based upon the results of physiological experiments, which cannot be quoted here, but which have never been discredited. It is no more surprising that the muscles of the nose or face should pass into contraction in paralysis of the facial nerve, than it is that the muscles of the œsophageal tube should exhibit vigorous contractions after section of its pneumogastric branches, expelling the food swallowed by "a peculiar kind of regurgitation . . . . a sudden antistaltic action of the parts" (Dr. Dalton's "Phys.," p. 473). See, also, Dr. M. Hall's demonstration of the active contractility of the œsophagus "after all its nerves have been divided" (Dr. Carpenter's "Hum. Phys.," p 404). These are results wholly at variance with the alleged paralysis of the œsophageal muscle, in which case it would be a mere flaccid tube, incapable of resisting or expelling its contents.

The state of contraction thus shown to be naturally expected, and actually to occur, in the nasal muscles from paralysis of the portia dura, may properly be regarded as present also in the larger facial muscles while equally undergoing a deprivation of nerve-force. Indeed, it is freely admitted by the authorities, that while, in some cases of facial paralysis, "scarcely any distortion is present," and the actual condition of the muscles is necessarily obscure and misleading, in other cases "tonic rigidity" is sometimes present (Dr. Hammond, ib., pp. 77, 78). In the facial incompetency due to cerebral meningitis, we may have "paralysis or spasms" (ib., p. 231). That is, as I have elsewhere stated, in mild forms of paralysis, the nerve, while no longer subservient to the will, has still power enough remaining to inhibit the contractile power of the muscle and to prevent it from passing into a state of spasm. The condition of spasm and rigidity attends the graver forms of paralysis, in which the restraining influence of the nerve is wholly arrested. Again, in the general paralysis of suppurative encephalitis (which surely gives extensive scope for paralysis, from the pressure of effused serum and pus), "one side of the face is permanently contracted" (ib., p. 249). That in less severe forms of paralysis of the portia dura, the facial muscles are also contracted, though obscurely so, owing to the slighter contraction producing less prominently marked distortion, is a natural and legitimate conclusion from the foregoing facts, the correctness of which is fully proved by an examination of the individual muscles.

Of these muscles the orbicularis oris is the chief. This muscle occupies a peculiar position, as compared with muscles generally. Its attachments are chiefly to other muscles, and its lateral halves, considered separately, may be said to be attached to each other. It is elliptical in form, and it appears to the writer that the behavior to be expected of it, and the symptoms which follow when one lateral half is deprived of motor-nerve influence, are quite consistent with the idea that this lateral half has undergone a degree of contraction, subject to the restraints of the much less powerful muscles which influence it.

Thus, the "paralyzed" lateral half, by condensation of its tissue, draws itself toward the median line as its *quasi* point of attachment. As a consequence, under the peculiar conditions, the resistance which, in its normal state, it offers to the other or healthy, half of the ellipse, may be regarded as lessened, giving to the median line a tendency, if not actually pushing it, toward the sound side of the face—a deviation which is also aided by the tonicity of the zygomatici and risorius of the healthy side, and by their contraction when movements of the face are voluntarily attempted, at which time the distention becomes especially apparent.

The complete shrinkage of the "paralyzed" half of the orbicularis upon itself is hindered by the similar contractile tendency of the risorius, zygomatici, and depressor anguli oris. But some of these are very weak muscles, and are only indirect opponents, so that, in spite of such resistance as they offer, the more powerful orbicularis effects a condensation of its tissue in the direction of its *quasi* attachment, the healthy half of the muscle. Notwithstanding this shrinking upon itself, on the part of the contracting lateral half of the orbicularis muscle, the chasm between the lips of the same side is only imperfectly closed, because the levator and depressor labii and depressor anguli oris are pulling at opposite parts of the muscular half-ellipse, preventing its full condensation and closure. As a consequence, fluids, as well as the breath and saliva, pass out here, giving a coloring to the popular idea that this portion of the muscle is relaxed. This view of the case fully accounts for the symptoms present, including the loss of the expression and the immobility of the features on the side of the paralyzed nerve.

But it is said that the buccinator muscle gives evidence of being paralyzed and relaxed, by permitting the flapping of the cheek during expiration. It is possible that this symptom may occur during moderate tension of the cheek, as well as during relaxation; and that it may be explained as a merely mechanical movement of the unsupported cheek. Drs. Todd and Bowman refer to it as occurring in the progress of protracted cases, where there is "great wasting of the muscles," in which the buccinator "becomes reduced to a mere inert membrane" ("Path. Anat.," p. 479), in which case, of course, the contractile power of the muscle (which is dependent upon its healthy nutrition) suffers greatly. This puffing of the cheek occurs, however, in more recent cases of paralysis, where time has not been afforded for loss of tissue, and even *in cases where there is no evidence of facial paralysis at all.* I am positively assured by several medical gentlemen, who claim to have witnessed it, and who would not hesitate to certify to the fact, that they have repeatedly seen this flapping of the cheek during the sleep or stupor of drunkenness, in subjects which at no time gave any evidence of paralysis. Some of Dr. J. W. Bennett's cases ("Clinical Lectures") furnish strong inferential evidence, at least, in favor of this statement. This symptom is so often mentioned by him as to justify the conclusion that it has not been omitted whenever present, and the cases are evidently reported with much care. The omission of any mention of it, notably in the 17th, 22d, and 27th cases, is, therefore, to be regarded as evidence that flapping of the cheek was not present, though the facial paralysis (from apoplexy) and the distortion of the mouth were well marked. In cases so obviously severe, the buccinator could hardly escape implication in the same paralytic process as the other facial muscles; and if the flapping depends upon paralysis and relaxation of this muscle, why is there no evidence of flapping here? Besides, it has not been shown that in the cheek, adherent as it is around its circumference, but free and unsupported in its central area, this flapping may not occur while its state is one of moderate tension. Indeed, no *proof* has been offered that the cheek or the buccinator is paralyzed and flaccid at all. It has been *assumed* to be so, merely as a mode of explaining the symptom, and that is all. A substantial reason why the buccinator muscle is not paralyzed in ordinary facial paralysis is to be found in the fact that it derives motor influence not only from the facial nerve, but also from the inferior maxillary, which supplies the masseter and other muscles of mastication, so that when the latter escape, as they usually do, the integrity of the buccinator is also pretty well assured.

It is also alleged, by all the writers on facial paralysis, that the buccinator muscle is relaxed in this disease because the food accumulates between the jaws and the cheek. Dr. Hammond, who himself adopts this view of the case, furnishes an involuntary illustration of how little dependence is to be placed on authoritative expositions, and how readily what are quoted in text-books as proofs of the existence of certain conditions can be modified, or reversed, by "the great masters" of pathology, when it becomes necessary to reconcile facts with the theory predominant in their minds.

The buccinator is under the motor control of the facial nerve, and consequently, in glosso-labio-laryngeal paralysis, this muscle is not "paralyzed." Nevertheless, here also the food accumulates between the jaws and cheek just as it does in facial nerve paralysis. Dr. Hammond, while admitting this fact, says: "This is not due to any paralysis of the buccinator muscle, but to the want of power of the tongue to move the alimentary bolus around the cavity of the mouth" (ib., p. 679).

The point here is that the food may accumulate in the cavity of the cheek when the buccinator is acting normally and is not paralyzed; consequently the alleged proof that the buccinator is paralyzed is no proof at all, and is merely an erroneous inference from "a scientific use of the imagination." If the reader (whose facial nerve is acting normally) will direct his attention to what occurs during mastication of his food, he will find that it passes freely into the space between the cheek and the jaws, but fails to remain there, owing to its very freedom while there, and to the free action of the cheek and lower jaw during the process. He will also find that the portion of food referred to is not ordinarily removed from the cheek by the action of the tongue, which does this only exceptionally, and when specially directed to it by an act of volition.

A little consideration will show that it would be impossible for the mucous membrane of the cheek to be so pressed against the alveoli as to exclude the food from passing between them during mastication; that such close adhesion would result in its being frequently bitten, and would besides materially interfere with the necessary movements of the cheek and lower jaw. That the food is retained between the cheek and the alveoli, in paralysis of the facial nerve, is undoubtedly true; but the facts, duly considered, show that this retention is due, not to a more than normal relaxation of the buccinator, but to the degree of undue contraction upon which its fibres have entered, on their nervous restraint being withdrawn; a contraction which does not prevent the food from passing between the cheek and the alveoli, but suffices, by the pressure it occasions, to retain it there until mechanically removed by the tongue or finger.

I cannot refrain from referring here, in the briefest manner, to the case reported by Drs. Beard and Rockwell, in their large work, in which, probably owing to the addition of the buccinator to the other antagonists of the orbicularis oris, the latter was overbalanced, and the mouth drawn toward the side of the paralyzed nerve, the muscles of which were notably contracted, and recognized as being so. Dr. Moritz Meyer, in his "Electricity in Prac. Med.," details several cases of peripheral facial paralysis, in which, amid "complete paralysis of one side of the face," the muscles displayed marked contractions. In Case 89, involving the left side of the face and the left nasal wing, the left levator was so rigid that it "could be felt from the inside like a tendinous cord." In the subsequent cases, the terms "stiffness," "rigidity," "spasms," and "contractions" are of frequent occurrence, as applied to the "paralyzed" facial muscles, of which the levators, depressors, and zygomatici were in one or other of these cases affected. These were examples of peripheral paralysis, chiefly due to cold and exposure, in which the muscles were promptly set free, owing to paralysis of their intramuscular motor-nerve endings; and hence the marked character of the contractions.

What have we to say about the obicularis palpebrarum remaining obstinately open in paralysis of the facial nerve, which furnishes motor control to this muscle? Why does it not assert its "inherent contractile power" and close the eyelid when its motor nervous restraint is thus withdrawn? In other words, if in the ordinary act of muscular contraction, there is a release of the muscle from nervous inhibition, by an act of the will, here, when this restraint is at an end, why does the muscle not avail itself of its involuntary freedom?

The orbicularis palpebrarum consists of two parts: the large muscular ring which underlies the eyebrow and extends downward upon the cheeks, and a more delicate and much smaller portion which covers the eyelids. The contractile power of the larger muscular ring finds an antagonist in the frontalis muscle, to which motor restraint is also supplied by the facial nerve. Hence, when the entire muscle is brought into action, the frontalis must yield, since not only the integument of the cheek, but of the forehead and temple, yields to its influence (Grey's "Anat.," p. 243). Paralysis of the facial nerve implies the setting free of the contractile power of its rival, the frontalis, and the pitting of this contractile power against that of the upper half of the ring of the orbicularis (its more active portion) prevents the descent of the eyebrow and the closure of this portion of the orbicularis.

It is only in forcible closure of the eyelids, however, that this portion of the muscle comes into play. The ordinary act of closure of the lid, as in voluntary and involuntary "winking," is performed solely by thin fibres stretched across the eyelids. These are in part composed of muscular tissue, and are under the control also of the sympathetic (Grey's "Anat," pp. 547, 625; Soelberg Wells, "Dis. Eye," p. 712). These sympathetic branches derive their motor power from the third pair (motor oculi), through the ciliary ganglion; and until the restraint which they exercise over the palpebral portion of the muscle is paralyzed, or nominally inhibited, this portion of the muscle is not free to contract, and consequently the eyelid remains open, notwithstanding the existing paralysis of the facial nerve, which, so far as it is concerned, has set the muscle free.

The significance of the view of the case just presented is materially heightened by facts bearing on the action of the eyelids in other diseased states. Thus, according to Dr. W. A. Hammond, while in paralysis of the facial nerve the eyelid remains *wide open*, in the paralytic stage of suppurative encephalitis the lid is "spasmodically closed" (ib., p. 249). That this closure is not due to the irritation of light is shown by the evidence of paralysis of the third nerve, as seen in the accompanying strabismus, double vision, etc. Now, the theory of the day teaches, and its adherents of course vigorously maintain, that it is *the muscles* which are paralyzed in the various forms of hemiplegia; and in paralysis of the facial nerve, that the *muscles* of the implicated side of the face are paralyzed, relaxed, and unable to contract, or even to maintain their ordinary "tone." Thus, in paralysis of the facial nerve, the orbicularis muscle of the eyelid remains open (it is said) because it is paralyzed; and, in suppurative encephalitis, in which the facial nerve is also paralyzed in the case we are considering, the orbicularis of the eye is necessarily paralyzed also, although here it is closed. The doctrine taught amounts to this: that in both these paralytic states it is *the muscle* which is paralyzed, with the result that in one case it remains persistently *open*, and in the other it is as obstinately *closed!*

The theory I am endeavoring to advocate leads to no such dilemma. As already stated, in simple facial paralysis the eyelid remains open, because its muscle although freed from the restraint of the facial nerve, is still subject to the control of the sympathetic branches which pass into it. In the severer paralysis of suppurative encephalitis, the eyelid is closed, because both the facial and sympathetic nerves are paralyzed, and the contractile power of the muscle is wholly set free and exerts itself accordingly.

The proofs have already been given that both the facial nerve and the third nerve, which supplies motor power to these sympathetic nerves, are paralyzed (Dr. Hammond, "Dis. Nerv. Syst.," pp. 248–249). The fifth, eighth, and ninth nerves are also usually involved in the same paralytic process (ib.). There is, therefore, of necessity an absence of nervous action as regards the "spasmodically closed" eyelid—a condition eminently in accord with our theory and with the propositions of Dr. Radcliffe, before quoted. But there is also here a condition diametrically opposed to the theory of the day, which demands "a preternatural stimulus" (Dr. Periera) from these paralyzed nerves, as essential to the muscular contraction which closes the eyelid.

The "twitchings of the muscles," "startings of the tendons," and "tremors" of the limbs, which are among the ordinary symptoms of this and other paralyzing diseases, are further evidence, not of "a failure of muscular power," but of the momentary exercise of that power, owing to the temporary failure of nervous restraint over the muscles—the property of contractility in which is comparatively independent of ordinary vital changes, and survives even the general death of the organism, displaying a little later, in rigor mortis, after the complete cessation of intramuscular nerve-force, "the most steady and persistent contraction which muscle can possibly exhibit" (Dr. F. Anstie, "Stim. and Nar.," p. 70).

A few words now as to the behavior of the tongue in states of paralysis of the ninth nerve, in which, on its attempted protrusion, it turns toward the side on which the nerve is paralyzed. The tongue is protruded by the action of the genio-hyo-glossal muscles, of which there are two, almost in juxtaposition, and are inserted longitudinally on either side of the median line along the base of the tongue. As usual, it is said that one of these *muscles* is paralyzed, and fails to push forward its side of the tongue, the lagging behind of which causes the deviation referred to.

The tongue is a compact organ composed of fibrous tissue and transverse and longitudinal muscular tissue. Its structure is therefore tolerably dense; and, from the closeness of the insertion of the two genio-hyo-glossal muscles along the whole length of the median line at its base, the action of either of these muscles might fairly be expected *to push forward the entire organ, provided its "paralyzed" side were entirely passive.* How true this is will appear from the following quotation from Dr. Carpenter, who says: "An instance has been communicated to the author by Dr. W. Budd, in which the hypoglossal nerve was completely divided on one side; and yet the tip of the tongue, when the patient was desired to put it out, was sometimes directed from and sometimes toward the palsied side, *showing that the muscles of either half are sufficient to give any required direction to the whole*" ("Hum. Phys.," note, p. 693).

The curve of the tongue on its attempted protrusion, is, then, not a proof that the corresponding muscle is paralyzed and passive, since such passivity would not necessarily prevent the protrusion of the organ in the usual way. Suppose that, as in the case of the other muscles mentioned, the muscle of the paralyzed nerve enters on a degree of contraction. The contraction of the *anterior* portion of the genio-hyo-glossus (which *retracts* the tongue), though unable to prevent the main portion of the muscle from protruding it, will yet materially retard this action, giving rise to the deviation under consideration.

That there is a strong justification for the explanation just given, will appear, not only by its precisely accounting for the situation, but also, from the fact stated by Prof. Kuss, that when the hypoglossal or motor nerve of the tongue is cut in a dog, the tongue "hangs out between his teeth," and the animal is unable to withdraw it within the mouth ("Lectures," Duval, Amory, p. 40.) Here is evident muscular contraction following directly upon section of a motor nerve, on which the champions of the theory of the day will no doubt feel called upon to reflect.

If the question be asked, why the contraction present in the muscles of the face, tongue, and œsophagus, during paralysis of their nerves, does not also occur with similar promptitude in the muscles of the extremities under similar conditions, the answer is probably to be sought in the fact that the nerve-trunks of the face, etc., are shorter, permitting a paralyzing wave more promptly to reach the terminal nerve-plates and nuclear reservoirs within the muscles, setting the latter free, than in the longer nerve-prolongations which pass to the muscles of the more distant extremities.

In the general view of the case here presented, the treatment of nervous paralysis, whether attended by simple motor incompetency without spasm, or when accompanied by muscular contractions or rigidity, would be properly directed to a restoration of nerve-force, as the natural antagonist to muscular contractile power. Remedial measures which reinvigorate the nervous system, temporarily or permanently, have proved the most effectual in the cure of tremor, spasm, or tetanic rigidity of muscle. So true is this, that Dr. Hammond attributes the palm to "stimulants" in the treatment of tetanus (ib., p. 541); and dilute alcohol is rapidly coming to the front in the spasms and contortions of strychnia poisoning (*Amer. Jour. of Med. Sciences*, Oct., 1879, p. 587). Such facts speak volumes for the theory here advocated, and are of course inimical in an equal degree to the theory of the day, as has elsewhere been more than once pointed out.

From the foregoing, it appears to the writer that the thesis with which we set out has been maintained; the theory put forward of the relations of nerve and muscle has been vindicated; and the striking symptoms of facial paralysis explained and accounted for on this theory, in full accord with the facts and the anatomo-physiological conditions present. It has also been pointed out wherein the theory now predominant fails to accord with, or to explain these conditions. All of which is submitted to the candid judgment of the reader.

In conclusion, may I be permitted to add, that I am well aware how utterly futile it would be, either for myself or others, to ignore the great principle that the interests of truth are paramount, and should never be compromised for the sake of supporting a theory, however favorite a one it may be. If my critics deem me culpable in this respect, I assure them that I am not intentionally so; and whatever my defects in this respect, *may I not hope to profit by their example* of fairness and love of truth?

SYPHILITIC DEGENERATION OF ARTERIES

As a Cause of Aneurism, with a Report of Two Cases.*

By NORMAN L. SNOW, A.M., M.D.,
ALBANY, N. Y.

These specimens are presented with the view of showing the deleterious effects of the specific disease "syphilis" on the arterial system in its last stage. It is acknowledged that syphilis is one of the most predisposing causes of aneurismal dilatation of the arterial vessels. The length of time, however, that the disease will remain dormant before effecting any degenerative change in the vessels is variable; also the period to which life may be prolonged after the formation of an aneurism, by nature strengthening the diseased artery—by throwing up new tissue or by filling the sacculated portions with fibrin or coagulum—cannot be definitely given. The important feature of the two following cases is the difference of time from the reception of the disease to death. In the first case it will be seen that death resulted within two years after the contraction of the disease, while in the latter sixteen years had elapsed.

Case I.—Miss Nellie B——, æt. 22, of medium size and good proportion, called at my office on March 5 (1880). She was at the time very weak, and appeared somewhat debilitated from the effects of the difficulty for which she sought advice. On questioning her she responded, giving the following history. Three years previous she had contracted syphilis, which was recognized as such by the appearance of a chancre. A few months later she gave evidence of having the secondary stage, which was manifested by the characteristic eruption, and a difficulty with the throat. The disease was seemingly controlled, and she began to improve, and enjoyed moderately good health, until about the first of January last, when she experienced some pain in the precordial region. This pain gradually increased in severity and duration, coming on in paroxysms, and her general health by degrees became reduced. The pain was so severe at times, when she exerted herself either in walking or otherwise, that she was compelled to support herself from falling. She described the pain during a paroxysm as being agonizing and lancinating; together with suppressed breathing, or, probably better described as if the chest-walls were constricted. She at times, during the interval between January 1st and March, felt moderately well, and at other times was compelled to take to her bed for a few hours or more. Such was her condition, which she described as varying from no particular uneasiness to extreme paroxysmal pains.

No evidence of previously existing disease was perceptible on the surface of her body or in the fauces. On percussion and auscultation, the lungs were found to be in good condition. In the precordial region, however, I detected a faint, or rather almost imperceptible bruit at the base of the heart. A few days later, the 8th inst., on examining a specimen of her urine, I found albumen, although no casts were detected. She did not call again until the 11th inst. Her condition was about the same, but her urine showed some improvement with her kidneys. I attended her at different times until the 20th, when I was summoned to see her in haste. I found her suffering with intense pain in the region of the heart, which extended to her left shoulder and arm. The pain was intensified during the paroxysms, which were of varying duration, and recurring at longer or shorter intervals. While laboring in one of these paroxysms, her body became livid, her face bore an expression of extreme anguish and fear, the pulse full and varying from eighty-five to one hundred, copious diaphoresis was notable, and respiration was greatly impeded and very irregular. The heart's impulse was almost imperceptible, and the pulsation of the right radial artery could be only slightly felt, while in the left it was entirely lost. On recovering from one of these paroxysms, she would sink into a state of complete exhaustion, the pulse would become rapid, respiration slow, shallow, and irregular, and diaphoresis markedly increased. She restricted her breathing somewhat, evidently apprehending that the pain would be intensified if a full movement of the chest was established. Any exciting cause, such as the barking of a dog, the unexpected movement of a door or window-blind, or any exertion, as in turning or getting out of her bed, would tend to bring on a paroxysm. To avoid any exertion, she remained perfectly quiet in one position, usually on her back. Pressure applied to the precordial region seemed to relieve her of pain very considerably. Her general health during the interval between the 20th of March and the 4th of April became very much reduced. Her urine was very scanty and high-colored, giving evidence of kidney difficulty. She experienced great thirst, and would drink any fluid given her. The remedies employed were anæsthetics, anodynes, and tonics, but these were only palliative in effect, if effectual at all, as they were, owing to a sensitive condition of the stomach, immediately rejected. Her condition remained about the same, and she continued to present the distinctive paroxysmal features each day until the 3d inst., when she stated that the pain was more especially beneath the sternum. This was excited by deglutition, and caused, as she described, a feeling of oppression in the œsophagus, and it was only with extreme care that she was enabled to receive any fluid into the stomach. Toward evening she appeared very much weakened, and remained in a fixed position on her back, until about five o'clock on the following morning, when she arose from her bed and crossed the room for some purpose and then returned. She requested a drink of water, which was given her, and in a few minutes later died.

Post-mortem.—Stomach normal in appearance, with the exception of a slight congestion of the mucous membrane in the greater curvature. Liver very large, with rounded edges; ecchymotic spots were present; very firm to touch and amyloid in character. Kidneys: left capsule adherent, irregular in shape, with slight depressions on surface; length 5 inches, width 2 inches, thickness 2 inches; very much congested, firm, and hard; cortical portion very thin; medullary portion very distinct; right: this was the same as the left in every respect, save that it was granular. Spleen normal. Ovaries enlarged and considerably congested. Omentum normal in proportion and apparently in a healthy condition. Bladder firmly contracted and in good condition. Uterus considerably congested; the round ligament and ovary on left side were firmly bound down to the posterior surface of the uterus; two small cysts were found on posterior surface of fundus. Lungs: the substance of each was apparently in a healthy condition; a few adhesions of pleura, no effusion. Heart notably larger than normal; the pericardium very much thickened and congested; no effusion in pericardial sac; the surface of the heart presented a few ecchymotic spots at its apex, with a fatty deposit at the base; the substance was soft, infiltrated with a fatty element, very flabby, and of a pale tawny structure; the walls of the left ventricle were thickened, while the reverse was the case with the right; the endocardium was somewhat hypertrophied, and the larger portion of it was of a pale color and flabby, while immediately beneath the semilunar valves it was of a yellowish white color and presented numerous atheromatous patches of recent origin; the semilunar valves were thicker than normal, and about the corpora arantii were found firm points or spots; a firm clot was found in both ventricles, the one in the right extended into the pulmonary artery, and the one in the left into the aorta. Aorta: this artery was dilated from its union with the left ventricle to the descending portion, thus involving the entire arch; it was fully twice as large as normal in diameter, and of varied thickness; at its junction with the left ventricle it formed a constricted ring, which produced a sac at the beginning of the arch; a ring of a similar description was also formed at its union with the descending portion; the arch, which formed the sac, was composed of coats of varied thicknesses; atheromatous patches were perceived in the inner surface of the arch, which was more or less nodulated; the coronary arteries were also dilated and their coats thickened and hard, so that they formed ridges over the surface of the heart.

---

* Read before the Albany County Medical Society.

The most striking feature of the changes in the aorta was the complete occlusion of the left subclavian artery by a small portion of the degenerative tissue which was firmly grafted to the inner coat. It can be readily seen why pulsation of the left radial artery could not be felt.

Case II.—I was called to see Mr. R. W——, æt. 39, of medium size, on the 28th of August, 1878. I found the patient, who appeared very much reduced, lying on an old dilapidated bed in a small, dark, filthy, and ill-ventilated room. He lay in a bending posture, with his legs flexed upon his body, as if endeavoring to alleviate the pain in his abdomen, which he described as excruciating and agonizing. I endeavored to get the history of his case, but owing to some impairment of his mind which evidently resulted from his low physical condition, failed to gather from him anything of importance regarding his condition in general. The parties who were in attendance, however, furnished me with the following history. They stated that a few months previous, he, while in company with some men in a boat on the river, was thrown overboard, evidently for their own amusement, and was considerably chilled. The following morning he complained of pain and some soreness in the lower right portion of his abdomen. In a few days this portion commenced swelling, together with increased pain, and gradually assumed its present proportion. For a number of weeks he was only able to move about on crutches, and in consequence of the severe pain was finally compelled to take to his bed. It was questionable whether his trouble was the sequel of the strain and cold he received at the time of his river experience or not, as there was no evidence that would elicit any information. He had been very much reduced by riotous living and had suffered in many ways from exposure.

On making an examination, a large tumor was found which occupied a position to the right of the medial line, the upper portion of which involved the lower part of the right hypochondrium and the whole of the right iliac region. The mass extended down the thigh beneath Poupart's ligament, as was seen by the somewhat constricted appearance of the tumor at the ligament. The walls of the abdomen were swollen and elevated, but not particularly prominent in any one portion, as is characteristic of different tumors. The skin was tense and presented a mottled appearance, and on placing my hand on the mass, it was found hard and resisting. The circulation was impeded by the pressure of the mass upon the veins, consequently there was great œdema of the thigh, leg, and foot. No movement or pulsation could be received from the tumor. Subsequently I learned, on completing the examination, that he contracted syphilis while in the army during the Rebellion, and that he had complained at various times of a stiffness, pain, and swelling in the region mentioned. He gave very little evidence of any constitutional disturbance, and his only complaint at this time was the severe pain, which he located immediately below Poupart's ligament and to the inner side of the thigh.

He was given anodynes, and warm fomenting dressings were applied, but he did not obtain any relief. He was admitted to the Albany City Hospital September 10, 1878. Dr. John Swinburne visited him in consultation with me, and he regarded the swelling as external to the pelvis or peritoneal cavity. He expressed his opinion that suppuration would take place below Poupart's ligament, from the appearance of the tumor, and advised that warm applications with oiled silk covering be extended well down on the thigh, to aid, if possible, an opening in this vicinity. This treatment was continued for a number of weeks, but no decided benefit was noticed. On the 18th of October the patient's symptoms gave evidence of an unfavorable termination. Drs. Albert Van Derveer and Samuel B. Ward saw him in consultation with me, and the prominent symptoms presented were as follows: he lay in a semicomatose condition, unable to assume a sitting posture or turn to either side in bed; responded incoherently to questions; sensibility greatly impaired in lower right extremity; obstinate constipation, pallor, and general emaciation, with atrophy of the muscles. This last condition effected a marked prominence to the tumor, which enabled us to see the exact extent of the growth. It appeared to involve nearly the whole of the pelvic cavity and the right half of the abdomen. There were no indications of the tumor opening externally, and fearing that it might rupture into the abdominal cavity, we decided to aspirate, knowing that he would die unless relieved. On the following day, in presence of Drs. Albert Van Derveer and S. H. Russell (resident surgeon), I introduced a small exploring-needle into the most prominent portion, and gradually pressed it well into the body of the tumor, a distance of three inches. The appearance of the fluid and the peculiarity of the flow convinced us in a very few seconds that it was best to withdraw the instrument. The needle had entered an "aneurism." No harm resulted apparently from the operation, as there was no decided change during the following month. His temperature continued varying from 99° to 106°, and his pulse, from 100 to 120. His bowels remained constipated, and his right leg became more and more œdematous from day to day, and his strength very much reduced; and finally, on the 9th of December, death relieved him of his suffering.

Post-mortem.—Examination was made thirty-six hours after death. Body extremely emaciated; rigor mortis well marked. I will not give in detail the condition of the different organs, as they were about normal, save kidneys, which were granular, with adherent capsules, and enlarged pelves, and liver enlarged and amyloid in character.

On making an incision over the body of the tumor the abdominal walls were found to be very thin, and firmly adhered to the growth. Dissecting the abdominal walls from the tumor, we found a small portion of the intestines lying upon the upper third of the mass, while the free portions were crowded into the epigastric region, displacing the stomach to the left. The right external iliac artery passed over the tumor, and was partially imbedded in it, and changed from its normal course downward. Owing to the immensity of the aneurism, and wishing to procure it without injury, we removed the entire mass by dividing the spine between the tenth and eleventh dorsal vertebræ, the pelvis at the symphysis pubis, and the left sacro-iliac synchrondrosis and the femur about six inches below the greater trochanter. The entire mass was then arranged so as to enable us to get the proportions of the aneurism and to study more exactly the character of the tumor. The proportions of the tumor I present you are as follows: length, 10 inches; diameter above Poupart's ligament, 7 inches, beneath the ligament, 3½ inches, below the ligament, 4½ inches. The aneurismal sac extended from the upper edge of the last dorsal vertebra to four inches below Poupart's ligament.

The coats of the internal iliac artery had evidently given away by the pressure near its origin, and as it increased in size burrowed its way beneath Poupart's ligament down on the thigh. The pouches which are found in different places are filled with fibrin and coagulated blood, and wall after wall of connective tissue has been thrown up; thus each pouch was prevented by the efforts of nature from rupturing until this large hardened mass was formed, presenting more the appearance of a solid growth than an aneurism.

In the etiology of disease probably no one cause commands a greater area for consideration than syphilis. The changes it effects on the human system present many very interesting features, one of which I here disclose in reviewing the foregoing cases. I do not intend, however, to discuss the constitutional peculiarities of syphilis further than its effects on the arterial system, as it does not appropriately become a part of the subject now before you. The arterial lesions of syphilis have been of late the object of much study and investigation; yet, the remarks which have appeared in print are somewhat brief and inexplicit, which leads one to infer that those who are interested in the subject question whether aneurisms are the result of this disease or not. The evidences clinically collected, however, furnish sufficient proof of the peculiar effects of syphilis. One author remarks: "Those arteries which are most prone to atheromatous and earthy degeneration are those which are most prone to aneurismal dilatation." The diseased or atheromatous condition of the artery by fatty degeneration into oil particles arises from an internal cause. Syphilis is evidently the most predisposing cause of this irretrievable condition of the artery. The middle or muscular coat of the vessel is mainly the seat in which the crystals of cholesterin and subsequently calcareous degeneration occur. The tissues in which these particles accumulate are gradually disintegrated with a deposition of a fatty or calcareous element. They are also subject to gummy infiltrations diffused between the coats of the artery for some length, thus thickening the same or developing in a distinct tumor. Gelatinous nodules may develop from the middle coat, and by their presence upon the internal coat decrease the calibre of the vessel. The inner aspect of the artery presents slightly elevated patches, yellowish and opaque, in the atheromatous stage of degeneration. They are seemingly covered with a thin membranous coat, which, as the degeneration advances, partially or completely gives way or disappears entirely. In the calcareous stage a destructive condition is effected as the artery becomes inelastic and brittle, and the patches assume the character of bony plates, but these have little or no osseous structure. The artery is disposed to yield to the pulsating action of the arterial wave-current, and develop into an aneurismal sac at the portion of the artery which has undergone a degenerative change, thus destroying its elasticity and contractility. Such was the condition of the internal iliac artery mentioned in the second case. Its entire continuity was destroyed and at different portions was developed into pouches, evidently owing to it not being able to resist the current pressure. The vessel may assume a calcareous character and remain rigid, and the particles of degenerated tissue progressively develop in size and subsequently occlude the blood-current. This condition was noticed in the left subclavian artery at its origin with the aorta, in the first case reported. The mass or patch was firmly adherent to the inner surface of the vessels and presented somewhat the appearance of a valve.

Aneurisms terminate fatally, either by rupture of the dilated portions, gangrene of the vessel, or constitutional irritation. In the two cases reported, death evidently resulted from the constitutional effects of the diseased condition of the arteries.

◆

THE BOYLSTON PRIZE.—The following are the questions proposed for 1881:

1. The effects of drugs during lactation, on either nurse or nursling.

2. Injuries to the back without apparent mechanical lesion, in their surgical and medico-legal aspects.

The author of a dissertation considered worthy of a prize, on either of the subjects proposed for 1881, will be entitled to a premium of three hundred dollars.

The questions proposed for 1882 are:

1. Sewer-gas (the gas found in sewers): What are its physiological effects on animals and plants? An experimental inquiry.

The author of a dissertation upon the above subject considered worthy of a prize will be entitled to a premium of three hundred dollars.

2. The therapeutic value of food, administered against, or beyond, the patient's appetite or inclination.

The author of a dissertation on the above subject considered worthy of a prize will be entitled to a premium of two hundred dollars.

ON THE RELATIONS OF DIPHTHERIA AND SCARLET FEVER.

Read at a Quarterly Meeting of the Tri-States Medical Association,

Held at Port Jervis, N. Y., July 14, 1880.

By J. H. THOMPSON, M.D.,
GOSHEN, N. Y.

There are, unexceptionably perhaps, no two diseases between which there exists so intimate a relationship as between the two which constitute the subject of discussion in the present instance. One so completely glides into the other, that we have the singular phenomenon of two disorders, generally described as distinctly separate, existing, apparently, in the same person at the same time. While one is not likely to err in his diagnosis when either disease appears in its clearly marked forms, yet it is quite often difficult in individual cases to determine whether it be one or the other in question. This observation is especially true in sporadic occurrences of attacks of these maladies. Among all the symptoms, there is no single one that would be completely indicative and pathognomonic in the diagnosis at all times. To particularize, the following may be noted as marked features of resemblance in a general way: The two diseases agree in their epidemic character, in the degree and course of their pyrexia, and in their chief points of attack, being the throat and skin. The etiology of the two, likewise, stand upon a common basis. Any one of the varied causes recognized as productive of the scarlet-fever poison, applies with equal force to diphtheria, and *vice versa*. The sequelæ of the two diseases are also similar: suppuration of the lymphatic glands; ulceration of the ears; arthritic affections, with or without cardiac complications; kidney disease, manifested by albuminuria and dropsy; general or local paralysis of the nervous system, etc. Each and all of these consequences have been met with after both diseases, yet the differences between them are too important and too numerous to permit of their effects being considered as different manifestations of the same disease. First, it may be asserted as capable of being maintained, in my opinion, that diphtheria may arise directly from scarlet fever, but that the converse of this proposition does not obtain. When the characteristic features of diphtheria occur coincident with the existence of scarlet fever, in any particular case, during a scarlatinal epidemic, I am inclined to believe that the former is to be viewed in the light of a complication, rather than as a distinctive disease. The diphtheritic invasion intercurrent with and aggravating an existent scarlet fever attack, finds its vulnerable point of seizure in connection with already invaded parts, namely, the organs of the throat; and when this happens, to wit, the formation of a well-marked exudative membrane in the fauces, it may be said, I think, with all propriety, that the distinguishing feature of the one disease is *engrafted*, as it were, upon the other general malady.

Another etiological phase of difference in the two diseases is this: diphtheria is less energetically contagious, and is more frequently associated with local causes than scarlet fever. It is conceded that both diseases, as to production and spread, have a close connection with unsanitary surroundings—such as exhalations from fecal matter, sewage gas, and the like pestilential agencies; but it is generally admitted, I believe, that diphtheria is more essentially dependent for its prevalence upon these morbific influences than scarlatina. Besides the marked difference just mentioned, it may be affirmed, I think, without cavil, that scarlet fever is more unmistakably dependent on the personal conveyance of infection for its spread. Then, again, I am of the opinion that seasonal influences exert an unlike agency in respect to the two diseases. The facts seem to justify the statement that scarlet fever prevails most in late autumn and early winter, while diphtheria is less dependent upon season; nor is it influenced by heat or moisture or locality. Still another point of difference between the two diseases is, that while scarlet fever is rarely associated with other complaints, diphtheritic affections are commonly met with in the course of various pyrexial disorders.

The most typical feature of scarlet fever is perhaps its accompanying rash. This is almost never wanting or undistinguishable. In diphtheria it is often, if not generally, absent, is very variable as to the time of its appearance, occurring seldom at the outset of the malady, and it may occur as late as the third week. Albuminuria is often found within two or three days after the commencement of diphtheria, whilst in scarlatina it seldom sets in until desquamation of the kidneys has commenced. There is an absence of definiteness about the duration of symptoms in diphtheria which marks it off from the regular sequence of events of scarlet fever; in the former, exudation may form on the fauces for six weeks or two months without much affection of the cervical glands. The mode in which diphtheria localizes itself on the mucous membranes or broken surfaces separates it from any other disease. Different epidemics differ widely in the point selected for attack; often the larynx and bronchi have been seized, as well as the throat, in diphtheria; but does scarlet fever ever attack the larynx? Furthermore, does an attack of diphtheria confer any immunity from subsequent seizures? The susceptibility of the throat, indeed, seems rather increased than diminished incident to diphtheria, while scarlatina seldom reappears in the same individual.

Without pursuing further an alternate contrasting of the two seemingly related maladies we have attempted to analyze, let us now consider briefly some of the special and phenomenal characteristics of diphtheria, which may tend helpfully toward settling its individuality as regards any other form of allied disease. Whether diphtheria is in the beginning a systemic affection or becomes a constitutional disease after, and in consequence of, the local lesion, is a question I shall not stop to discuss; but I do not hesitate to declare it to be, in my judgment, due to a *contagium vivum*, or living microscopical fungus, that gets entrance into, and grows at the expense of, the animal fluids. The nature of diphtheritic contagion, it seems to me, has been microscopically demonstrated—demonstrated as satisfactorily and conclusively as it has been demonstrated that carbon and zinc, when placed in contact with sulphuric acid, will generate a force which in physics is called electricity.

This wonderful triumph of discovery of the true causation and real pathology of diphtheria was the outcome of the labors of Heuter and Oertel. They simultaneously made the discovery that the diphtheritic membranes, the subjacent diseased parts, and even the blood of diphtheritic patients, contained in great numbers vegetable organisms, so-called bacteria, to which Oertel gave the name of micrococci. The significance of vegetable parasites in diphtheria and diphtheritic contagion has been subsequently and further proved by numerous other distinguished investigators. Microscopical examinations of the exudative membrane of diphtherial patients have invariably disclosed nides of micrococci, and large colonies of these organisms, in numerous instances, have been discovered in the brain and other organs of those who have died of diphtheria.

Independently of the argument incidentally introduced, having relation to the etiology of diphtheria, from an unbiased consideration of the facts and evidences germane to the general question bearing upon the differential diagnosis of the two diseases which we have essayed to consider, it may be justly concluded, I think, that, while they furnish many points of resemblance, the features of unlikeness, as to nature and symptoms, are too great to allow us to rank them as identical.

Progress of Medical Science.

Amputation of the Cervix Uteri.—A discussion took place recently in the *Société de Chirurgie*, Paris, concerning the best instrument for this operation. Most of those who took part in it favored the galvano-cautery, on the ground that the thermo-cautery produced too much heat and smoke, while the knife was dangerous on account of the hemorrhage it caused. —*Jour. de méd. de Bordeaux.*

Prevention of Secondary Hemorrhage.—Dr. Parona, of Bologna, considers that the essential condition for the success of ligature or torsion of a blood-vessel is the formation of a clot, and this he proposes to effect more rapidly and certainly by the injection of a few drops of hydrate of chloral into the lumen of the artery. The usual ligature may be placed on the vessel, or two ligatures may be used and the chloral injected into the portion of the artery enclosed between them. He tried a variety of substances, but found chloral superior to all others as a coagulating agent, the resulting clot fitting much more closely the calibre of the vessel, and not shrinking as does that yielded by perchloride of iron. He performed numerous experiments on dogs before venturing to practise his method on the human subject; he has lately, however, tried it in two cases with excellent results. Besides acting as a hæmostatic, the chloral acts also as a sedative, and thereby exerts a favorable influence from the first on the progress of the case.—*London Medical Record*, April 15, 1880.

Polypi in the Frontal Sinus, unassociated with similar growths in the nasal fossæ, are of great rarity, while in conjunction with nasal polypi they would appear to be not so extremely infrequent. Dr. H. Knapp contributes the following interesting case of polypi and accumulation of pus in the right frontal sinus, with successful operation. Patient stated that six years previously his right eye began to be pushed down, forward, and outward. The protrusion had gradually increased. A tumor was felt in the upper inner corner of the eye four years ago, and had since been growing slowly but steadily. When he presented himself, Dr. Knapp found the eyeball displaced forward, down and outward, its motion restricted up and inward. A round tumor, about the size of a walnut, occupied the upper inner corner of the orbit. Its centre felt soft, its periphery hard and in some places bony. It was immovably connected with the periosteum. The tumor throbbed when pressed upon, but it did not increase when the patient stooped. V. R. $\frac{20}{40}$, L. $\frac{20}{20}$; no diplopia. The interior of the globe was normal. Aside from occasional headache, there were no cerebral symptoms present, nor was there any abnormity discoverable in the nasal passages or the molar antrum. Dr. Knapp diagnosed periosteal sarcoma with osseous spicula and softened portions, a kind of tumor which he has several times observed on the roof of the orbit in young people, even in children. The patient was operated on, February 9, 1878. A curved incision was made below the orbital margin, from the middle of the lid to the roof of the nose. On cutting deeper, a large quantity of offensive pus was liberated from a cavity which, when probed, proved to be the dilated frontal sinus and the upper anterior ethmoid cells. The thinned and defective bony orbital wall of the cavity was then broken down with a chisel and strong scissors, and fragments of bone were removed. On further exploring the abscess-cavity with a probe and the little finger, a considerable amount of soft tissue was felt on its inner wall. It was extracted with a pair of polypus-forceps. This substance had all the appearances of mucous polypi, which diagnosis was afterward confirmed by microscopic examination. A part of the wound was left open, a drainage-tube put in, and the wound was covered with charpie. The patient made a good recovery. The correct diagnosis in this case was almost an impossibility before the operation. Even after the defective bony shell of the tumor was broken into, the doctor had no suspicion of the presence of polypi, which were unexpectedly discovered while investigating the extent of the abscess-cavity and the condition of its walls. The frontal sinus and the anterior ethmoid cells must have been shut off from the nasal passages, since there was no discharge from the nose and no ozæna before or after the operation, and the liquid injected into the abscess-cavity never entered the nose. The recovery of the patient was certainly very gratifying. If a fistulous opening had remained, or in case matter should collect again in the frontal sinus, the proper treatment would be to re-establish the communication between the sinus and the middle nasal passage, by breaking through the ethmoid cells and inserting a seton or tube for a sufficient length of time—several months —as W. Bowman and others have done.—*Archives of Ophthalmology*, June, 1880.

Contributions to the Pathology of the Frontal Sinuses.—Dr. H. Knapp reports the following interesting case: The patient, a female, æt. 30, had suffered for two years from attacks of headache, which lasted from several hours to a whole day. The pain sometimes extended along the nose, though she had never shown any symptoms of nasal catarrh. This pain became more intense, and was eventually localized on the left side of her forehead and in the left orbit. The outer half of the supra-orbital margin was red, swollen hard, and painful to the touch; the eye was moderately pushed forward and inward; the pupil responded to light; vision was unimpaired, and the ophthalmoscope discovered only a slight venous congestion of the retina and some circumpapillary œdema. Drs. Knapp and J. Lewis Smith left the diagnosis undecided between dacryo-adenitis and periorbitis, and ordered mercurial ointment to be rubbed into the skin surrounding the brow. The pain continued, the swelling increased, and two days later the presence of a large abscess pointing at the juncture of the middle and outer thirds of the upper lid, about a centimetre below the brow, was manifest. The abscess was opened and a large quantity of creamy pus let out. The patient felt relieved and apparently recovered rapidly. Six days afterward she felt worse again, complaining principally of headache. She grew very feeble, vomited, and lay mostly in stupor. Her pulse varied between fifty and sixty. In this condition she was found by Dr. E. C. Seguin, who was called in consultation nine days after the opening of the abscess. The upper lid slightly drooped, the internal rectus was paretic, and the ophthalmoscope revealed only congestion of the retina. Dr. Seguin diagnosticated an abscess in the left frontal lobe of the brain. Two days later the patient died. The autopsy showed that the frontal sinus had extended laterally so as to separate the cranial from the orbital plate of the horizontal part of the bone. The flat cavity produced in this way had a height of from four mm. to six mm. at the inner upper corner of the orbit, and reached, gradually decreasing, as far as the junction of the middle and outer thirds. The orbital plate was brittle and broken when removed from the cadaver, so that the perforation through which the pus had escaped from the sinus into the orbit could not be demonstrated; but, judging from the place where the swelling first appeared and the abscess pointed, there was no doubt that the perforation of the bone occurred at or near the temporal end of the extension of the frontal sinus. Such an extension of the frontal pneumatic cavity through the diploëtic substance of the roof of the orbit occurs frequently enough in cases of caries of the supra-orbital margin, and this case suggests the idea that pent-up pus in the ethmoid and frontal cells may be the cause of the caries in some of the cases. Knapp does not, however, think of explaining in this way the frequency of caries of the upper orbital margin in children, since the frontal sinuses, according to Dursy and Steiner, develop only between the sixth and eighth years.

That in this case there had been an inflammation with retention of matter in the left frontal sinus, was clearly proved by the periodic attacks of headache starting from the inner part of the left brow. The narrow and irregular communication of the frontal sinus and anterior ethmoid cells with the middle nasal passage, through the upper end of the infundibulum, must have been closed, since the patient did not suffer from nasal catarrah or ozœna. The propagation of the disease into the orbit and brain was a perfect analogue of what is so frequently noticed in retention of matter in the mastoid process. There, also, the narrow exit of the mastoid antrum into the tympanic cavity is closed, periodic inflammations ensue, occasionally an abscess emptying into the drum-cavity or behind the ear gives temporary relief; at last the patient dies, and an abscess is found in the brain-substance, sometimes at a distance from the temporal bone. In the case under consideration the channel by which the inflammation extended to the brain was clear, as there was a necrosed patch of bone in the cerebral plate of the horizontal process of the frontal bone, and the adjacent dura mater was blackened and somewhat wrinkled. The description of the cerebral abscess will be given by Dr. Seguin.—*Archives of Ophthalmology*, June, 1880.

Benzoate of Soda in the Treatment of Gonorrhœal Ophthalmia.—Prof. Dow, of Berne, reports a case of gonorrhœal ophthalmia, which he treated with the benzoate of soda. He was led to try the remedy by his belief that a micrococcus exists in the pus of purulent conjunctivitis, whether of the blennorrhagic or the diphtheritic form. In the case reported, both eyes were affected and threatening speedy destruction. He prescribed a solution of benzoate of soda (1 in 20), one of tannin (1 in 10), and another of tannin (1 in 100), as an eyewash. The first two solutions were dropped into the eye every ten minutes, and the wash was used to remove any discharge as soon as it would appear between the lids. On the seventh day the eyes were practically well, although they did not tolerate broad daylight. A month later they were perfectly well. Dr. Dow has also employed this method of treatment for two years in all cases of ophthalmia neonatorum, with a like success.—*Dublin Journal of Med. Science*, June, 1880.

Salicylic Acid as an Anthelmintic.—Dr. Tlyin has used this acid successfully in a number of cases of tænia. He begins with ℥j. of castor oil in the evening. In the course of the following day the patient takes from ʒ ss. to ʒ j. of salicylic acid, and in the evening another dose of castor oil. Only in a single case was it necessary to repeat the treatment. —*Meditz. Obozrenie*, April, 1880.

Apomorphia in Sunstroke.—Drs. Tomlinson and Murphy call attention to the value of the hydrochlorate of apomorphia in the treatment of sunstroke. In three very severe cases the drug was administered as soon as possible after the admission of the patients to the hospital, $\frac{1}{16}$ grain being sufficient to produce the desired emesis in two of the cases. The vomiting occurred in less than ten minutes after the injection; in no case was there any distressing nausea, but apparently an almost instantaneous evacuation of the contents of the stomach. The temperature was reduced, and the pupils became widely dilated, while sensation and movement returned within half an hour. The skin became slightly moist, and the patient regained consciousness by slow degrees. In each of the cases there was complete insensibility; eyes fixed, pupils contracted to the size of a pin's head, and insensible to light; pulse very full and rapid; breathing shallow, stertorous, and accompanied by moaning; temperature very high (109° in one case), and involuntary evacuation of the bowels. —*The Practitioner*, June, 1880.

The Pathology of Herpes Zoster.—M. Chandelеux, of Lyons, publishes, as a contribution to the pathology of herpes zoster, the notes of a case of zona occurring in the track of the second and third intercostal nerves of the left side in a phthisical subject. The eruption persisted for several months before death. The lungs were extensively diseased, and very adherent to the chest-wall, the adhesion being most firm and dense on the left side, opposite to the point of emergence of the second and third intercostal nerves. The subjacent intervertebral ganglia were notably swollen, nodulated, and pigmented. Microscopically these ganglia showed large tracts of sclerosis replacing nerve-cells and fibres, but it was observed that the bundles of nerve-fibres belonging to the anterior roots were healthy. The tissue in the sclerosed parts was disposed in concentrically arranged bundles, which interlaced with one another, and were surrounded by numerous pigmentary granulations. The outer portions of the sclerosed tracts were infiltrated with small round cells, contrasting with the denser and more organized connective tissue of the central parts. There were but few vessels in the new tissue. The intercostal nerves were hardly, if at all, involved in the morbid change, which is somewhat inexplicable, if the ganglia be considered to be the trophic centres of the posterior nerve-roots. There was no degeneration, no atrophy of nerve-fibres in the intercostal nerves, corresponding to the altered areas in the ganglia, such as might reasonably be expected to be found. No changes were found in the main trunk and ganglia of the sympathetic. The cutaneous lesions consisted of bullæ of varying size, some located between the Malpighian and corneous layer of the epidermis, others between the epidermis and the dermis itself. The contents of the bullæ were granular serous material, blood-coloring matter, etc. The author publishes the details of this case because of the very marked character of the changes in the intervertebral ganglia.—*London Lancet.*

Parasites in Muscle in Typhoid Fever.—Two cases of parasites existing in the voluntary muscles of patients with typhoid fever have been reported to the Pathological Society of London. The first case was that of a young man in St. Thomas' Hospital, who died from peritonitis set up by perforation of a characteristic enteric ulcer. In the pectoral muscle were found what were taken to be parasitic worms, one or more of which were seen in each specimen; apparently, from their movements, they were still alive. Their dimensions were wholly different from those of trichina spiralis, being about a quarter of it in length and breadth. They were thickest in the middle, with one end larger than the other. They resembled nematoid worms both in the proportion of their breadth and length, and in the presence of an interior canal, apparently interrupted by some intervening organ or tissue. The other case occurred in the Seaman's Hospital, and on examination of the muscles the same bodies were found. In neither case, however, were the parasites so plentiful as was at first supposed. They were found in all muscles equally, except in the diaphragm, but they were not uniformly disseminated through a given muscle.—*London Lancet*, April 24, 1880.

General Hygiene and Therapeusis of Posterior Sclerosis.—Dr. Weir Mitchell contributes an excellent article to the May number of the *Philadelphia Medical Times*, on the general hygiene and therapeusis of posterior sclerosis. As regards treatment by drugs, the writer claims to have seen good results from two drugs—nitrate of silver and iodide of potassium—and of these the latter has given the best results. In France there is still some belief in the value of the mineral waters of La Malon in L'Hérault, but the slight experience he has had with them has not been encouraging. The question of hygiene is considered next. There is a period, and a long one, in which the ataxic is able to enjoy life to a considerable extent, before his powers of locomotion fail. It is in this stage of the disorder that it is most important for him to live by certain rules, which are not at all those which should govern healthy people. The great heats of our summers are very hurtful to these patients, and no class of people seem to benefit more than they by changes of climate. The situations which suit them best in summer are moderate elevations, such as the foot-hills of the Alleghanies, or Saratoga, or the Adirondacks. The seaside or cold sea baths are undesirable. The somewhat mysterious group of aerial states which accompany or constitute storms are most distressing to many ataxic neuralgics. Like the traumatic neuralgics some of them can predict storms with certainty, and begin to feel their baleful influence long before the rain belt reaches them. The general sensibility of ataxics to storms and cold makes it, therefore, needful for them to exercise unusual care in avoiding abrupt changes of temperature and in watchfully suiting their dress to the season. As to exercise it may be said that all of this class of persons should zealously avoid fatigue, and that many of them are the better for not walking at all. In such ataxic persons as are at all sensitive to the influence of exercise, any unusual exertion is apt to be followed by slight increase of strabismus, by sense of lassitude, and by definite increase of neuralgia and of the disorders of co-ordination. The patient should be well rubbed once a day. The objects are to excite locally the circulation, to empty thoroughly all the vessels within reach, to flush the whole limb so as to raise its temperature, and to stimulate vigorously the muscles so as to give them, at least for a time, the tone they lack. Ataxics are not especially liable to dyspepsia, but they are forced to take aperients from time to time. A pill of aloes and irridin, or of aloes, ox-gall and belladonna, answers usually, or suffices if aided by an enema. Tobacco has a decidedly hurtful influence on most ataxic patients. It were best avoided altogether. The hygiene of the sexual organs is a far more important matter. In some few cases the loss of virile power comes very early, and is well marked; but the writer knows of many ataxics who have had children after their disease became well marked. At La Malon, where Dr. Privat sees a great number of posterior scleroses, the prohibition of all sexual intercourse is absolute and peremptory.

Affections of the Bones in Leucæmia.—Prof. Neumann, of Königsberg, reports two cases of leucæmia, which he had recently observed, and in which the osseous marrow was ascertained to have undergone marked degeneration. Leucæmic disease of the bone marrow is not commonly recognizable during life, at least such has been the experience of the author and several other German writers. The first case recorded by Neumann was that of a man æt. 41, who was first seen in 1876, when he suffered from a large carbuncle in the right lumbar region. Some time after his recovery from this, he began to develop symptoms of leucæmia, and in 1877 the disease was found to be quite pronounced. The point of interest was the supervention of pain in the left shoulder and sternum, followed, at a later period, by extreme aching in the right thigh. Objective symptoms were not discoverable in any of these localities. At the autopsy the sternal marrow yielded, on pressure, a thick, dirty, brownish looking fluid in great abundance. The right humeral diaphysis showed a dark-red marrow, in which numerous yellowish-green spots, resembling purulent collections, were found to be disseminated. These patches were especially abundant at the external portions of the medullary substance. The marrow of the spongy tissue in the humeral epiphyses exhibited no alteration.

The second case presented no intra vitam symptoms of bone disease, and in this respect resembled the majority of cases hitherto reported. Notwithstanding this, however, the osseous marrow was also found to have undergone considerable changes. In all the bones which could be examined, *i.e.*, the sternum, ribs, and the diaphysis of one humerus, the medullary substance appeared as a pulpy, dirty-red material, resembling pus mingled with blood. In this marrow, as well as in the patient's blood, nucleated red blood-globules and Charcot's crystals were easily demonstrable. Dr. Neumann finally reiterates his belief in the close causal relation existing between these osseous changes and leucæmic disease—a subject which he has previously considered at some length in the *Berlin klin. Woch.*, 1878, Nos. 6, 7, 9, and 10.—*Berlin klin. Woch.*, May 17, 1880.

The Physiological Effects of Erythrophleine.—Drs. G. Sée and Bochefontaine publish the results of a series of experiments undertaken with this drug at the laboratory of the clinic of the Hôtel-Dieu. Erythrophleine, it will be remembered, was discovered in 1876 ("Arch. de Phys. et Soc. de Biol.," 1876) by Gallois and Hardy. It is the active principle extracted from the bark of *erythrophleum guineense*, and was found to be an alkaloid of powerfully toxic action and peculiar effect upon the heart. It was the latter circumstance which induced the authors to believe that the new drug might possess therapeutic properties to be utilized in cardiac affections. The experiments were made on various animals, but the writers describe only the effects produced on rabbits and dogs by the hypodermic injections of fixed quantities of erythrophleine. It was found that one-sixth of a grain administered to a dog weighing eighteen pounds produced no appreciable effect, whereas one-third of a grain proved fatal to a dog weighing twenty-nine pounds. The toxic power of erythrophleine was ascertained to be about equal to that of the amorphous digitaline of Homolle and Quevenne.

The first signs of intoxication consist of slight agitation and restlessness, followed by a period of depression, which is the forerunner of attempts at vomiting, or actual vomiting. These symptoms rapidly disappear, if the dose has not been too large. In addition, the blood-pressure is augmented, the pulse becomes irregular, and its frequency is diminished. This period is characterized by the regularity of the cardiac beat, by the energy of each pulsation, and by the uniformity of the arterial blood-pressure. The latter is no longer modified by the respiratory movements, as is normally the case. Following this period, there comes a stage of extreme feebleness of the pulse, with marked acceleration of its beat. Respiration again causes oscillations in the blood-pressure, which gradually diminish, the heart's action grows more and more feeble, ceases momentarily, is again resumed, and finally stops altogether, while arterial pressure sinks to zero.

Respiration appears to be directly influenced by erythrophleine, and at the same time is indirectly modified by the cardiac effects just described. At first the respiratory movements are retarded and become more ample. In the final stage of intoxication, when the heart beats with great frequency, the breathing becomes very energetic, and the number of respirations is considerably increased. Sometimes respiratory movements continue for a short time, even two or three minutes, after cardiac action has ceased.

Faradic excitation of the peripheral portions of the pneumogastric nerves in the cervical region did not interfere with the heart's action. Hence it seems that the cardiac inhibitory action of this nerve is paralyzed by the drug. Stimulation of the cephalic portion of the nerve, in an advanced stage of intoxication, did not increase the frequency of the pulse (as it normally does), but raised the arterial tension. After the animal died the heart was found in diastole, and generally its electric contractility remained intact. The writers' experience with this new drug, in the treatment of heart disease, will be submitted to the Academy at a later period. We may expect some valuable facts to be brought to light by these indefatigable investigators.—*La France médicale*, June 16, 1880.

The Causes and Treatment of Leucorrhœa in Children.—M. Bouchut recently delivered a clinical lecture on this affection, which is of greater frequency than is generally supposed. Among the causes of leucorrhœa in children, he placed in the first rank vulvar irritation, from whatsoever cause. Under this head lack of cleanliness deserves the foremost place, as many mothers, rich as well as poor, believe that daily ablutions of the genitals are unnecessary. Bouchut, however, claims that the female glands, like the preputial glands of the male, furnish a secretion, which, when allowed to accumulate, invariably causes irritation, and thus gives rise to leucorrhœa. Onanism and attempted violation are enumerated among the local causes of leucorrhœa. Constitutional influences, such as the various diatheses, are also said to be of etiological importance. The treatment is both local and general. Under the former heading Bouchut mentions: first, the greatest possible cleanliness of the affected parts, to be obtained by frequent washings with mildly astringent lotions; and, second, the alteration of the diseased surfaces by lotions or hip-baths of a $\frac{1}{30}$ % solution of corrosive sublimate, or by a $\frac{1}{2}$ % wash of carbolic acid, or by the application of weak silver nitrate solutions. After each washing a pledget of charpie, dipped in coal-tar, or covered with the ointment of the red oxide of mercury, should be placed between the labia. Various medicated baths are also serviceable. The general treatment varies with the diathesis of the given case.—*Gazette obstétricale*, June 20, 1880.

A New Method of Treatment for Varicose Ulcers.—Dr. F. Borel-Laurez, surgeon to the Providence Hospital, at Neufchatel (Switzerland), has published what he considers a simple and effectual method of treating varicose ulcers. This method consists in simply powdering over the surface of the ulcer with charcoal. A piece of charcoal is heated to incandescence in a furnace or stove, and then allowed to cool slowly. Those particles which are not completely charred are put aside, and the rest is ground between two sheets of rough paper. until a fine powder results. Previous to use, this is passed through a sieve. Before employing the powder, the ulcer is washed with tepid water, dried, and all hemorrhage carefully arrested. Then the charcoal is spread out over the entire surface of the ulcer by means of a spatula, and covered with a compress secured by a bandage, which is allowed to remain in place for two days. The powder is then washed off with a jet of water, and the former process repeated. This is continued until cicatrization has well advanced, and the ulcer presents the appearance of a mere abrasion of the skin. Then, to avoid all friction, which might interfere with proper epithelial development, the charcoal is replaced by a piece of Lister's protective, which is to be renewed every second day. When the cicatrix has formed, compression is practised by enveloping the leg with moistened bandages up to the knee. This is kept up until the cicatrix is firm enough to bear the friction of shoes and stockings.—*Le Réveil médical*, June 5, 1880.

Abortive Treatment of the Inflammatory Stage of Gonorrhœa.—Dr. Kuechenmeister, of Dresden, has found aqua calcis, when properly diluted, extremely serviceable in the first stage of acute gonorrhœa. He uses it in the proportion of one to four of water, and employs injections, beginning about the fourth day after an impure coitus, and repeated every hour or hour and a half during the entire day. Usually, the acute inflammatory symptoms subside after about twenty-four hours, but the copious, painless, discharge from the urethra is not lessened, and the treatment, although aborting the first stage, must be replaced during the second stage by the ordinary astringent therapy. Dr. Kuechenmeister prefers, for the latter purpose, a solution of pure alum (10) in water (150), to be injected two or three times daily. He also advises great care in the handling of the lime-water, to prevent its spoiling by the formation of carbonate of lime, through the access of air. The bottle containing it should, therefore, be tightly stoppered, and only enough fluid removed to suffice for one injection. Moreover, none of the fluid removed should be returned to the bottle.—*Deut. Med. Woch.*, June 5, 1880.

Nocturnal Terrors in Children.—An analysis of Dr. Wertheimber's description of this malady, by Dr. Gottardi, contains the following therapeutic points: All causes of nervous excitement should be carefully avoided, especially during the hours immediately preceding bed-time. Bland and scanty supper, without stimulating drinks, such as tea or coffee. A room sufficiently large and moderately lighted, in order that the child may, on waking, immediately recognize the surrounding objects. Quinine and bromide of potassium, to the latter of which some chloral may be added, are the drugs which have proved most serviceable. The general health of the child or infant should also be improved by a suitable regimen, including tonics, open air exercises, and gymnastics.—*Arch. Méd. belges*, May, 1880.

Tendinous Suture in Transverse Fractures of the Patella.—In referring to the method of Kocher (*Centralbl. f. Chir.*, No. 20, 1880), which is intended to replace Malgaigne's method of employing a clamp in patellar fractures, Dr. Volkmann takes occasion to give his own manner of treating these accidents. It resembles Kocher's, inasmuch as both gentlemen employ a tendinous suture. But Volkmann believes that it is not necessary to pass the silver wire through the joint, as has been recommended by Kocher. It will suffice, he thinks, to pass a single loop through the tendon of the quadriceps, and another through the ligamentum patellæ, taking care to observe all the necessary antiseptic precautions. The suture is to remain in situ until complete union will have occurred. To insure a perfect contact of the fractured surfaces, the joint should be punctured, and any existing fluid or blood withdrawn. This should be done as early as possible, and before the application of the suture.—*Centralbl. f. Chir.*, June 12, 1880.

Intermittent Articular Dropsy.—Dr. Seeligmüller records a case of intermittent dropsy of several joints, occurring in a patient who was under his observation since 1875. The disease existed twenty-five years. The patient had had an attack of typhoid fever in 1846, a pneumonia in 1849, and was seized in the same year with intermittent fever, lasting seventeen weeks. In 1855 he suffered from a painful tension, affecting alternately the left knee- and hip-joints, lasting about one day or thirty-six hours, and occurring every twelve days. The attacks were accompanied by moderate swelling of the knee-joint. After continuing for some time they gradually disappeared, but returned again with greater severity in 1861. This time the patient was afflicted with them for three months. He suffered again in 1865, then in 1872, and since the year 1875 has never been quite well. A very severe attack, with considerable articular tumefaction, was observed in 1879, and resisted all medication. The most prominent symptoms of these seizures were the painfulness and the swelling of the knee-joint. Severe attacks would depreciate his general health, but a rise of temperature was never observed. The usefulness of the joints had not been impaired.

In addition to this case, Dr. Seeligmüller mentions twelve other cases, which he has collected from various sources. All these cases have certain symptoms in common: an otherwise healthy adult is attacked at regular intervals, without prodromal symptoms and without assignable cause, by a painful tumefaction of one or both knee-joints. The absence of all inflammatory symptoms, as well as of any febrile movement, appears to be characteristic of these seizures. The swelling is marked by a stage of increase (stadium incrementi), by a stage of stability (stadium acmes), and by a stage of decline (stadium decrementi). The rhythm of recurrence varies from an eight days' type to one of four weeks' interval. Quinine and arsenic have been recommended, but an effectual and reliable therapy has not yet been found. Seeligmüller finally admits that the true nature of these attacks is not yet definitely known, although, personally, he is inclined to regard the disease as a vaso-motor neurosis.—*Centrabl. f. Chir.*, June 19, 1880.

Inoculability of Tuberculosis on Animals.—M. Toussaint has decided, by means of a series of experiments, a question that has been long in doubt, viz., the possibility of the tubercular infection of animals by means of ingestion and inoculation. It is an admitted fact that tuberculosis is almost unknown among swine. M. Toussaint, however, has been able to produce tuberculosis in the pig almost at will. In some of the experiments the animals were made to eat the lungs of tuberculous cows; in others, the fluid scraped from the cut surface of tubercular nodules was injected subcutaneously, and in still others the blood of a tuberculous pig was injected; under all these different conditions the tubercle was always reproduced. The lesions thus produced were those of acute tuberculosis, and they always proved fatal in a very short space of time—a few weeks. The tuberculosis of swine is analogous to the galloping consumption of man.—*Jour. de méd. et de chir.*, May, 1880.

Benzoate of Soda in Whooping-Cough. — Dr. Tordeus, of Brussels, writes that he has prescribed the benzoate of soda in a number of cases of whooping-cough, and that in all the cases the parents reported that the coughing fits began to diminish in force and frequency after one or two days of treatment. He gives four grains of the salt every hour to a child of two or three years. The drug seems not alone to diminish the force and frequency of the paroxysms, but also to exert a favorable influence on the mucous membrane of the respiratory tract, and to prevent the development of serious pulmonary complications.—*Journal de méd., etc., de Bruxelles*, May, 1880.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, August 28, 1880.

THE DETERIORATIONS, ADULTERATIONS, AND SUBSTITUTIONS OF DRUGS.

In a report recently made to the National Board of Health on the the subject of deteriorations, adulterations, and substitutions of drugs, Dr. C. Lewis Diehl has presented a large number of facts which should have much interest both to physicians and pharmacists. As preliminary to certain elaborate statistical tables which he has compiled, Dr. Diehl gives a brief history of the drug market in this country. It is shown that, since the law of 1848, prohibiting the importation of impure drugs, there has been an enormous amount of adulterated articles kept out of the country. Such protection to home industries, naturally stimulated the business of adulteration among American manufacturers. Through the persistent efforts largely of the American Pharmaceutical Society, however, frauds in the drug market have been considerably checked, and its present condition is, according to Dr. Diehl, unqualifiedly fair. By this is meant not that poor and adulterated drugs are absent in the market, or that inferior medicines are not dispensed in our pharmacies; but that persons who really wish articles of standard quality have very little difficulty in getting them. This qualification, of course, applies especially to pharmacists. When it comes to stating what patients can get and what is the quality of the drugs actually given out to the public from the retail stores, we doubt whether so favorable a view can be taken. There are a good many elements tending to make the prescription matter of the average retail druggist below the degree of quality which may be designated as "fair." The law against importing inferior drugs is, confessedly, in many ports not carried out rigidly or intelligently. The desire of the patient to get his medicine at the lowest rates, and the desire of the druggist to make all the money he can, tend, with an immense force, to encourage adulterations in the preparation of drugs at home, as well as substitutions and deteriorations in the articles sold at the shops.

The tables given by Dr. Diehl show some of the principal inferiorities in drugs which have been discovered and reported upon in the current literature of the past thirty years. In commenting upon these statistics, some facts in regard to forms of preparation most frequently adulterated are given. Thus it is stated that powders present the most successful field for sophistication; and, owing to their physical condition, it is often difficult to detect the foreign admixture. So systematic has been the practice of adulterating powdered drugs, indeed, that in many drug mills regular formulæ for the preparation of pure and genuine powders have been, and probably still are, in use. As an example, a popular formula for powdered opium was: "Turkey opium, 50 pounds; Egyptian opium, 25 pounds; biscuit, 40 pounds." Rhubarb is a drug which, in a powdered form, it has been customary to adulterate. The volatile oils have been, and still are, shamefully adulterated. All the cheap grades of the tarry oils, of lavender, rosemary, and red thyme have been greatly adulterated with turpentine. The galenical preparations of the shops are not well spoken of by Dr. Diehl; and he corroborates the fact, which every physician must know, that infusions and decoctions are often made simply by mixing the fluid extract with water. The worst that can be said of tinctures, fluid extracts, and solid extracts is that they are generally liable to vary in strength.

It is, of course, hardly possible to get a very definite idea of the commercial quality of the medicines as dealt out over the counter. We can tell something in regard to this, however, by a study of the drug market, and by comparing the reports of individuals or committees who have made special examinations into the matter. From tables thus compiled we learn that, out of a list of two hundred and twelve drugs, which includes about the whole materia medica, one is pronounced very good; seventy-three good, fifty fair, thirty-three variable, and nine very indifferent. The quality of the remaining forty-six depends upon various conditions, but good articles can for the most part be obtained if the buyer desires it.

A survey of all the facts presented leads us to one at least very plain conclusion: that the purity of our drugs depends almost entirely on the honesty of our druggists. Good drugs are obtainable if they will only be obtained. We should by no means, however, secure pure drugs by simply preaching morality. The druggist cannot be expected to ignore the laws of business and make himself an isolated spectacle, of moral grandeur. There must be laws, better executed than the present, for preventing foreign importation and home manufacture of inferior drugs; there should, we believe with Dr. Diehl, be legal restrictions upon the profession of pharmacy, which would secure to it a higher educational status and a more definite responsibility to the state. Finally, and this is the part which especially concerns medical men, it should be the practice of physicians to see that their prescriptions are filled with pure drugs. This is a point about which many physicians are much too careless. And it is one which, if actively attended to, would do more than all else to secure purity in the drug market. If physicians insist that their patients get their medicines at reputable places, even though the price is slightly greater, such reputable places will increase in number. It would be easy to teach the patient that establishments which advertise to undersell various staple drugs are unsafe. Such instruction and a more active attention to the proper filling of his prescriptions, form a part of the duties of the physician.

RECENT DENTAL CONVENTIONS.

The activity among the dentists has been unusually great during the past few weeks. The American Dental Association held an annual meeting at Boston, August 4th, 5th, and 6th; the American Dental Convention and the Southern Dental Association met in this city, August 10th to 14th. These two latter associations united to form a National Association under the name of the Dental Association of the United States. This association is expected to be the representative body of the American dentists. It will hold annual meetings in different cities, and quadrennial meetings in Washington, where its permanent secretary is to reside. The Association aims at high scientific work, and will arrange at once to secure governmental recognition to the dental profession, and help from it in studying ethnological peculiarities in their relation to dentistry. The Smithsonian Institution promises aid in this direction.

A vote was passed making it a requisite for membership that the applicant should have credentials from a State society, or the diploma of a reputable dental college. This latter regulation, it is expected, will give an impulse to dental education.

The new association was not formed without some opposition. The American Dental Association has tried to have a national character, and it refused to allow its organization to be absorbed in any other. But its work and membership, if we may believe the reports, have been of a too local character. It was therefore decided to form an entirely new society. Any genuinely scientific work done by the dentists will be of value to the medical profession. If this new association, therefore, secures, as it promises, the performance of such work, its creation will be a matter of congratulation for us.

We have examined the reports of the various meetings above referred to, and confess to being greatly disappointed in our hopes of finding any good scientific work performed. In the American Dental Association there were papers devoted to the relative merits of cohesive and non-cohesive gold, the respective values of which, it seems, ought to have been settled long ago; the use of belladonna to lessen the flow of saliva, catarrh in its relations to dentistry, and the evil effects of the various patent amalgams, were some of the topics presented. We noticed a paper on Anæsthesia, which was defined to be a "paralyzation of the nervous tissue." In a subsequent discussion on the subject, the question as to whether nitrous oxide oxidized the blood, or prevented its oxidization, was discussed. The fact was brought out very strongly that the Association did not know anything about the matter whatever. A practical movement was made in the appointment of a committee to arrange for an International Dental Congress. Considerable time was devoted by the American Dental Association to the discussion of dental education. Of course the question whether dentistry was a branch of medical science was fully debated. We quote and commend the remarks of Dr. Barrett on this point: "We dentists," he said, "should be honest. We are not medical men, and are not acknowledged as such by physicians. There is no way by which a student can become a member of the medical profession, except through a medical college." The Association urged that the dental colleges require a higher preliminary medical education and two courses of instruction.

We find even less evidence of work at the New York conventions than at that held in Boston. The daily papers perhaps gave undue prominence to certain parliamentary infelicities, but these were certainly much too frequent for the credit of the societies.

Most of the time was given to excursions and the business of organizing the new association. An interesting paper was read before the Southern Dental Association, on Mercurial Poisoning Caused by Sucking the Amalgam of a Mirror. Not much else of general scientific value, however, was presented.

It will probably strike any one who reads the reports of the dental conventions to which we have been referring, that American dentists are persons sadly deficient, as yet, in scientific as well as in parliamentary knowledge. Their meetings have, however, shown a commendable appreciation of deficiencies and desire for progress. And considerable work was done which will eventually secure scientific and educational advancement in dentistry.

REGULATING THE PRACTICE OF PHYSIC.

We take this occasion to call the attention of our readers, especially such as reside in this State, to the act regulating the licensing of physicians and surgeons, published in full in another column. On a former occasion we gave a full synopsis of the provisions of said law, and explained in some detail the purposes for which it was enacted. It is only necessary at this time to give the simple text of the law, in order that the physicians of this State may understand what is expected of them. It will be seen that each and every one practising physic must, on or before October 1, 1880, register in the Clerk's Office of the county in which he resides, his name, residence, place of birth, "together with his authority for so practising physic and surgery," and that the "fee for such registration shall be twenty-five cents, paid by the person so registering." Further, it will be seen that such as fail to register will be subject to a fine of fifty dollars. Although this may be considered by many practitioners as somewhat of a burden, it should nevertheless be cheerfully borne, in view of the good to be accomplished in the direction of suppressing all kinds of quackery, as tending to protect scientific medicine. We are glad to learn that in many of the different towns throughout the State the registration is far advanced, and that there is shown a general willingness to comply with the provisions of the law. It is not necessary to present a diploma to the clerk, as an affidavit as to time and place of graduation will be accepted in lieu of it.

Although it must be admitted that the law is by no means a perfect one, it is the best that can be obtained for the present, and the profession throughout the State should do its utmost to aid in carrying out its designs.

A Thousand Ovariotomies.—On June 11th, Mr. Spencer Wells performed ovariotomy for the one thousandth time. Out of his first 500 cases, 127 died, a mortality of 25.4 per cent. Of the next 300 cases, 77 died, giving a mortality of 25.6 per cent. Of the next 100 cases, 17 per cent. died; and of the last 100 cases, 11 per cent. died. Mr. Wells began to use antiseptic precautions shortly before the beginning of the last 100 cases. The grand total of all the operations gives 768 recoveries and 230 deaths. According to certain calculations made on the basis of life insurance expectancy, 22,272 years of human life have been added to society by the direct agency of Mr. Spencer Wells.

Kindergartens as a Cause of Myopia.—It is asserted that a good deal of the play-work at kindergarten schools taxes the eyes of the child to an undue extent. Examples of this are, the pricking holes along a tracing on a paper; or braiding bright-colored bands of paper; or the sewing fine silks along other fine tracings. Myopia is quite as likely to result from this kind of work as from study.

A Homeric Physician.—Dr. Dunbar, a physician in a small town in Scotland, has written an elaborate concordance to the Odyssey and Hymns of Homer. Mr. Gladstone at once recognized the value of the work, and has placed the doctor on a pension of £80 a year. Dr. Dunbar recently published an article on the Medicine and Surgery of Homer.

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Sixth Annual Meeting, held in New York, June 16th, 17th, and 18th, 1880.

Wednesday, June 16th—First Day—Afternoon Session.

The Association convened at the Academy of Medicine, in the city of New York, at 2.30 p.m., and was called to order by the President, Dr. F. T. Miles, of Baltimore.

The names of the following gentlemen were presented for membership: Drs. Graham M. Hammond, of New York, Isaac Ott, of Easton, Pa, W. R. Birdsall, of New York.

The first paper was by Dr. William A. Hammond, of New York, entitled

MYXŒDEMA, WITH SPECIAL REFERENCE TO ITS CEREBRAL AND NERVOUS SYMPTOMS.

Myxœdema was a disease which had for its pathoanatomical feature the deposit of a mucoid substance in various parts of the body, especially in the skin, or a degeneration and proliferation of the connective tissue. Probably both these conditions coexisted in some tissue. The tissues were resilient and not boggy, as in ordinary œdema, though the resulting appearance was very much the same. The face resembled the appearance resulting from toxic effect of arsenic. The fingers were clubbed at their extremities. The temperature was always below normal. The disease thus far had occurred in adult women. The cerebral and nervous symptoms appeared to be very decided. Dr. Hammond gave a detailed account of a case which had come under his observation, both as to the general appearance of the patient and the general symptoms presented. Dr. Hammond was of the opinion that the mental symptoms were the result of primary brain disease, probably to the deposit of the mucoid tissue around the cells of the nervous centres. He considered, however, that both central and peripheral disturbances were necessary to give rise to the phenomena of myxœdema.

The paper was discussed by Drs. Jewell, Miles, and Hammond.

SWOLLEN AXIS CYLINDERS IN MYELITIS—SPECIMENS.

Dr. S. G. Webber, of Boston, presented some specimens to be looked at under the microscope. A history of the case from which they were taken was given. The specimens presented very well the enlarged axis cylinders. There were the other appearances of myelitis in the dorsal region, and nearly the whole length of the spinal cord was softened so that sections could not be made. As many as eleven or twelve enlargements have been observed upon one axis cylinder. The medullary sheath seemed to have disappeared, and when much swelling existed there was no appearance of myelin whatever. In transverse sections all exposed axis cylinders appeared in groups. Sometimes these enlargements occurred in chronic cases, but never in so marked a degree.

Dr. Jewell had seen quite a number of acute or more or less acute cases of this kind within the last year or two. Several of his cases of acute myelitis were produced in much the same way; they were due mainly to exposure. One case which came under his notice had been treated with large cases of ergot, under the idea that the blood-vessels would be contracted and thus relieve the patient; instead of this, however, he got worse. Dr. Jewell placed him on large doses of strychnine and increased the doses almost up to toxic ones. The man had improved so that now he could almost walk. He had given as much as one-tenth of a grain of strychnine three or four times a day. He insisted upon the patient having absolute rest.

Dr. Hammond agreed as to what had been said in regard to rest, but what Dr. Jewell said in regard to the use of strychnine, he confessed, shocked him. He did not see how anybody could keep quiet who was taking one-tenth of a grain of strychnine four times a day. It struck him as a very dangerous practice.

Dr. Gray said that a point that interested him was, when to stop rest. It was undoubtedly of benefit in the early treatment of myelitis, but he had seen cases where he believed it had been carried too far. He thought it difficult to determine the effect of strychnine in these cases, for they had not been studied particularly. He had had excellent results during the use of iodide of potassium, but he had not been able to state that it was the result of the drugs.

Dr. Seguin referred to a patient in whom complete paralysis developed within ten or twelve hours after the first symptoms. Microscopical examination showed destructive changes rather than swelling; a great many of the ganglion cells had undergone a vacuole formation. He thought we were approaching a classification of acute myelitis into two forms, one an active or parenchymatous, and another where the connective tissue was primarily affected, and in which we found those areas of disintegration. He did not believe that any amount of strychnine, ergot, or iodide of potassium would cure destructive myelitis. Dr. Jewell had not given us the symptoms which enabled us to judge of the treatment, and in particular the muscular reactions to faradism. If his cases were those in which the anterior horn was involved, it was not surprising that no muscular contraction occurred under strychnine. A few of these cases of affection of the anterior horns got well spontaneously.

Dr. Putnam believed that it was recognized that poisons acted very differently upon diseased nervous centres from what they did upon normal tissue, and he thought that in speaking of strychnine, we were using as a basis nothing more than physiological experiments. Dr. Hammond had never seen a case of myelitis which was not aggravated by the administration of strychnine. He suggested that the effect produced in Dr. Jewell's cases might be due to the administration of a larger dose than usual; opposite effects were produced by the same drug by varying the size of the dose.

Dr. Bartholow thought Dr. Jewell's cases were syphilitic, and upon that theory we could account for the rapid improvement under the iodide of potassium and the beneficial influence of strychnine. After the syphilitic products were removed by the iodide of potassium the tissues needed the subsequent stimulus of strychnine. He believed, however, that strychnine could only aggravate in acute myelitis.

Dr. Jewell said the point he wished to make was, that after the case had progressed to a certain extent, we might begin the use of strychnine, and that too, much earlier than was ordinarily supposed possible. His cases were not syphilitic.

The paper was farther discussed.

Dr. J. J. Mason, of Newport, R. I., next proceeded to read his paper, entitled:

MICROSCOPICAL STUDIES ON THE CENTRAL NERVOUS SYSTEM OF REPTILES AND BATRACHIANS—DIAMETERS OF THE NUCLEI OF THE CELLS IN THE SPINAL CORD.

Extended observation enabled him to formulate the following law which he predicted would be found to hold true in all vertebrated animals:

"The nuclei of the cells in the inferior (anterior) horns, in the two enlargements of the spinal cord, have averaged diameters which are proportional to the muscular power of the corresponding extremities." From observations made he inferred that the nucleus of a motor-cell grows with the muscular substance which it is supposed to enervate.

Dr. Spitzka remarked that it had long been known that cells in different parts of the cord differed in size. He did not believe that any fixed relation could be established between the cells and the muscles through which they were distributed.

Dr. Hammond inquired if reflex excitability was not greater in the posterior group of cells than in the anterior?

Dr. Mason thought not.

Dr. Hammond took exceptions to this and declared that reflex excitability was greater in the sole of the foot than in the palm of the hand, and the hind legs than in the fore legs.

Dr. Mason remarked that as far as sensation went it had nothing to do with the subject of the paper.

There being no further discussion, Dr. Robert Bartholow, of Philadelphia, read a paper entitled:

THE TRANSFER OF SENSATIONS.

Two years ago Dr. Bartholow, while practising hypodermic injections into the painful points in a case of sciatica, had his attention called to the fact that if a patient felt pain in the arm of the same side simultaneous with the pain at the point of puncture, the patient always referred the pain to the corresponding position on the upper member of the same side, and never on the other side. Further investigation was now resolved upon, and to this end an ordinary sewing needle of large size was used to develop the initial pain, and ice wrapped in oil silk to produce the local lowering of temperature. It was found that the fall of temperature produced by the refrigerations of a member affected the corresponding region of the same limb on the opposite side, and that these deviations of temperature were never greater than one-half of a degree. The explanation was to be sought for in the connection of the vasomotor system with the spinal. The experiments which were submitted indicated that the transfer of painful sensations were limited to the same side. Pain of considerable severity, though not prolonged, was necessary to develop secondary pain.

Dr. Putnam alluded to some experiments he performed upon the frog, in which he irritated one foot of the animal, and caused the blood-vessels in the other foot to contract. Ice applied to one ear of a rabbit would cause a temporary rise of temperature in the other.

Dr. Beard had noticed, in applying the faradic current to the right leg, its effects were also observed on the corresponding site of the left leg.

This condition he considered pathological rather than physiological.

The paper was further discussed by Drs. Jewell, Spitzka, and Miles.

First Day—Evening Session.

The Association was called to order by the President at 8.30 P.M.

The first paper was by Dr. Landon Carter Gray, of Brooklyn, on

THE USE OF QUININE WITH THE NERVOUS SEDATIVES.

He maintained that quinine, when given with the bromides, belladonna, and hyoscyamine, lessened the depression that these drugs usually produced, while it actually increased the effect of these medicines over the diseases for which they were given, as epilepsy, mania, etc., whilst in the conjoined use of quinine with the nervous sedatives, this curious fact had not been hitherto observed.

Dr. Jewell said that whenever there was nervous or muscular weakness in epileptic patients, he was accustomed to use strychnine, and found it exceedingly beneficial in combating the depressing effects of a prolonged course of the bromides. It did not increase reflex irritability.

Dr. Bartholow said that, as a rule, bromides were not as efficient in weak and anæmic patients as in others, unless they were combined with tonics; and chloral had the opposite effect upon the brain from the bromides, causing hyperæmia rather than anæmia.

Dr. Seguin quoted Brown-Sequard, and said that he had often impressed him with the danger of giving quinine in epilepsy, believing it was liable to precipitate the attack. He gave strychnine. Dr. Seguin had given quinine in some cases without apparent bad effect.

Dr. Miles expressed the opinion that there was no danger from bromism.

Dr. Spitzka recited the history of a case which led him to the conclusion that bromides did good only in emergencies.

Dr. Hammond thought that every atom of quinine added to a dose of the bromide lessened the effect of the bromide upon the patient. He did not know of a single combination that was beneficial to the patient, except the combination of Fowler's solution with bromide to prevent acne. When the effect of the bromides was injurious the best way was to reduce the dose. He had had four cases of death from the use of bromide. The combination of iron with bromides in epilepsy, he thought did harm.

Dr. Spitzka remarked that not for five years had he prescribed the bromide of sodium; he gave the bromide of potassium.

Dr. Seguin said he had found iron to work well in practice. He said that one of the chief actions of strychnine was to increase arterial tension; hence its efficacy in bromism, one of whose chief elements was weakening of the heart, and lowering of the arterial tension.

Dr. Hammond had seen the best results from the use of a certain amount of bromide of sodium in a certain amount of water.

Dr. Spitzka remarked that there could be no doubt about the antagonism of tonics and bromides; quinine reduced the action of the bromides.

Dr. Seguin recommended the dilution of each dose of the bromides with Vichy water. It covered the taste somewhat. For poor patients, a pinch of soda in the water would do very well.

The next paper read was by Dr. S. G. Webber, of Boston, upon

WATER AS A PROPHYLACTIC AND A REMEDY.

Many people had a notion that it was injurious to drink at meals, but a moderate quantity of fluid taken at meal-time was rather beneficial than otherwise. A large class of patients were affected with symptoms of an indefinite character—a vague unrest, showing itself by discomfort or even pain, sometimes in one place, sometimes in another. They were usually subject to constipation, often had an unhealthy hue of the skin. They were frequently classed as hypochondriacal or hysterical. There was no well-defined disease. These patients usually drank too little water. The waste of the tissue-changes in the system must pass into the blood, and could only leave the system in a state of solution. During comparatively good health, the amount of blood was maintained at nearly the same figure, and only so much water would be parted with through the skin, lungs, and kidneys as could be restored from other sources. If too little water was ingested, the perspiration would be slight, the elimination of urine would be diminished, and the excretion of waste material would be lessened. The blood would be continually saturated, or nearly so, with the results of disassimilation. The removal of the waste of tissue-changes was not accomplished with sufficient regularity, and the tissues became clogged with used-up material, and nutrition was interfered with. The balance each day against health was very slight; but after a time there was such an accumulation that unpleasant symptoms were developed. If the person continued to eat heartily, either the surplus food passed off by the intestines, or was deposited in the shape of fat, the nitrogenized portions assisting to load the urine with urea and the urates. Let such a person drink a large amount, and the blood, having a sufficient supply of water, more urine would be secreted, the loss made good to the blood by absorption, and a larger amount of waste products would be taken up to be eliminated; more urea or phosphoric and sulphuric acids passed off by the urine, which was increased in amount, and there was more disintegration of the tissues. This last was made up by new material, so nutrition was increased. The doctor found that neurasthenic patients did not drink enough.

Dr. Beard remarked that he had found thirst a prominent symptom of neurasthenic patients. He had been using Summit water with good results. He used the bromides alternately with tonics and a free supply of water. The plan was very satisfactory.

Dr. Webber said that patients who drank no more than a pint or twenty ounces of water per day, had told him that they were not thirsty, and were surprised when he told them to drink more water. These directions being complied with, the patients, in the course of the week, developed thirst, and drank as many as three pints a day.

SPHYGMOGRAPHIC TESTS.

Dr. James A. Putnam, of Boston, made brief mention of some experiments he had made in connection with Dr. Bowditch, in testing Pond's Sphygmograph. He had substituted a spring for the weight usually used, and found the instrument to work better.

Dr. Putnam then read a short paper on

STRETCHING THE FACIAL NERVE FOR SPASM.

From experiments on dogs, he had made up his mind that stretching of the nerve by means of a hook was the best plan; and, secondly, that it was best to let the patient come partly out from under the influence of the ether, and then pull just enough to cause a slight, immediate effect, with the expectation that no further bad effect would be produced.

THURSDAY, JUNE 17TH—SECOND DAY—AFTERNOON SESSION.

The Association was called to order at 2.30 P.M., by the President.

REPORT OF THE COMMITTEE ON NOMINATIONS.

Dr. Jewell presented the report of the nominating Committee, which was as follows: President, Dr. Roberts Bartholow, of Philadelphia; Vice-President, Dr. John C. Shaw, of Brooklyn; Secretary and Treasurer, Dr. E. C. Seguin, of New York; Councillors, Dr. S. G. Webber, of Boston, and Dr. Frank P. Kinnicutt, of New York. The above-named gentlemen were duly elected.

The Council reported favorably upon the candidacy of Dr. G. N. Hammond, of New York, and Dr. Isaac Ott, of Easton, Pennsylvania; elected.

The first paper of the afternoon was by DR. GEORGE M. BEARD, of New York, entitled

EXPERIMENTS WITH THE "JUMPERS" OR "JUMPING FRENCHMEN" OF MAINE.

This June he had visited Moosehead Lake, and found the jumpers and experimented with them. He found that what had been claimed was true, and more than true. One of the jumpers, while sitting in his chair with a knife in his hand, was told "Throw it," and he threw it quickly, so that it stuck in a beam opposite; at the same time he repeated the order to "throw it" with a cry, or utterance of alarm, resembling that of hysteria or epilepsy. He also threw away his pipe when filling it with tobacco, when he was slapped upon the shoulder. Two jumpers standing near each other were told to strike, and they struck each other very forcibly. One jumper, when standing by a window, was suddenly commanded by a person on the other side of the window to "jump," and he jumped straight up, half a foot from the floor, repeating the order. When the commands are uttered in a quick, loud voice, the jumper repeats the order; when told to strike, he strikes; when told to throw it, he throws it, whatever he has in his hands. Dr. Beard tried this power of repetition with Latin and out-of-the-way English words, and the jumper repeated or echoed the sound of the word as it came to him, in a quick, sharp voice; at the same time he jumped, or struck, or threw, or raised his shoulders, or made some other violent muscular motion. They could not help repeating the word or sound that came from the person that ordered them, any more than they could help striking, dropping, throwing, jumping, or starting. All of these phenomena were, indeed, but parts of the general condition known as jumping. Other sudden sounds, not proceeding from human beings, gave rise to the same phenomena. All the jumpers agree that it tires them to jump, and they dread it; but they were constantly annoyed by their companions.

This disease was analogous to the mental or psychical hysteria, the so-called "servant-girl hysteria," which was so often observed during the epidemics of the Middle Ages. It was a transoidal condition—a temporary trance, induced by reflex irritation and the emotion of fear. In a certain sense, we were all jumpers; an alarm of fire in a crowded building would have the same effect upon very many of us, producing trance with convulsive movements. An approximative analogue was to be found in the "Jerkers" or "Holy Rollers," those who, under religious excitement, rolled upon the floor, as observed in Northern New Hampshire; but the phenomenon of jumping differed from the above analogues: first, in the temporariness and momentariness of the phenomenon; and, second, in the persistence of the liability. Psychologically, these jumpers were modest, quiet, retiring, deficient in power of self-assertion and push. Women were rarely jumpers. Jumping was hereditary, and restricted mostly to a class of people in the northern part of New Hampshire and Maine, and in Canada. The disease was probably an evolution of tickling—the habit of tickling each other in the woods. In regard to prognosis, Dr. Beard said: "Once a jumper, always a jumper." Dr. Beard claimed that his theory of trance, as explained in his work upon that subject, explained this phenomenon of jumping.

The paper was discussed by Drs. Gray, Jewell, and Beard.

CERVICAL PACHYMENINGITIS.

DR. V. P. GIBNEY, of New York, read a very valuable and interesting paper upon this subject, which consisted of the detailed histories of three cases occurring in children.

DR. PUTNAM asked for more symptoms, which would enable one to differentiate between pachymeningitis cervicalis and Pott's disease. He wished to know whether it was possible to distinguish between the two, especially when there was no deformity.

DR. GIBNEY said that it was impossible to make a differential diagnosis at one examination. As a rule, you did not get spinal tenderness in Pott's disease, whereas this was present in pachymeningitis. If you had paroxysms of torticollis, you might be sure that the case was not one of Pott's disease. The paraplegia was alike in the two diseases, but there were very few cases of cervical paraplegia in Pott's disease. You could examine the posterior wall of the pharynx, in most cases, very well, and thus satisfy yourself in regard to the existence of bone disease.

Next followed the reading of a paper by DR. WM. A. HAMMOND, of New York, entitled:

THALAMIC EPILEPSY.

Dr. Hammond was convinced that there was no true epilepsy without loss of consciousness. In this regard he did not agree with Dr. Hughlings Jackson. This was an essential phenomenon, without which there was no epilepsy. The other symptoms were the characteristic features by means of which differentiations were made. The cases under consideration were marked by unconsciousness; but the other symptoms were of such a character as to exclude them from any one of the categories mentioned by Dr. Jackson. That the optic thalamus was the centre for perception, as the cortex was for intellection, was, to say the least, exceedingly probable. Every sense had, then, two stages in its full action: something was observed—that was one stage; it was more or less thoroughly understood, and that was another stage. The intrinsic starting-point of every sensorial impression was an organ of sense, such as the eye, the ear, or the terminal ramifications of the olfactory nerves. The starting-point of an erroneous or false sensorial impression, illusion, or hallucination, might be either the organ of sense concerned therein, or the sensory ganglion of the optic thalamus. It could only elaborate the impressions which reached it from the sensory ganglion, and these were either true or false, real or unreal, according as they came originally from the ganglion, or were transmitted through it from an organ of sense receiving real impressions from without; and, according as the cortex was in a normal or abnormal condition, would the ideas or beliefs which they formed from these transmitted impressions be normal or abnormal. All, therefore, that the cortex did, was to take cognizance of present or former sensorial impressions which it receives, or has received from the optic thalamus, and to form ideas from them. An additional argument against the involvement of the cortex was found in the fact that there were no muscular spasms in either of the cases cited. Spasms were, of course, not epilepsy; but muscular spasms combined with unconsciousness made a true epileptic paroxysm. It was thought, from what had been said, that the following conclusions were fairly deducible: first, that there was a form of epilepsy the phenomena of which were simply hallucinations and loss of consciousness; second, that the morbid anatomical basis of this type was located in the optic thalamus.

Dr. **Miles** remarked that he could not agree that the optic thalamus was the centre of observation.

Dr. **Jewell** regarded the thalamus as the seat of consciousness, and that the seat of perception was in the cortex of the brain. He had no doubt that the optic thalamus was intimately connected with the sense of sight. He thought Dr. Hammond was right in saying that sense perceptions came through sense organs, with one exception, and that was when inherited.

Dr. **Webber** thought it was possible for certain states of the optic thalamus to excite hallucinations, or that the cortex alone might excite them, and hence the vision seen. He took exceptions to the restrictions made by Dr. Hammond in the definition of epilepsy.

Dr. **Gray** thought that the view that the optic thalamus, and this alone, could be the seat of epilepsy, was unwarrantable, though it might be correct.

Dr. **Hammond** referred to certain cases of hallucination where the patients died, and the lesion found was located in the optic thalamus. There was not a single case on record where a lesion of the optic thalamus was found after death, in which there were not hallucinations of sight.

Dr. **Isaac Ott**, of Easton, Pennsylvania, next read a paper upon

THE BROMIDE OF ETHYL AS AN ANÆSTHETIC.

That the bromide of ethyl had a rapid and powerful action on the nervous system, was evident from its quick anæsthetic effect. In rare cases it could produce epileptiform phenomena. As an anæsthetic, he said it would seem to give excellent results when pushed to the extent of elevating the pulse and arterial tension; but the moment it depressed the tension and the pulse, then, in some cases dangerous symptoms might intervene.

Dr. Ott gave an exhibition of Woroschiloff's instrument, and explained its working. The instrument was for making sections of the spinal cord in living animals.

FRIDAY, JUNE 18TH—THIRD DAY—AFTERNOON SESSION.

The Association was called to order at 2.45 P.M., by the President.

The Secretary read the minutes of the preceding meeting, which were approved.

The Council reported favorably upon the name of Dr. W. R. Birdsall, of New York; unanimously elected.

Dr. **Gray** presented resolutions relative to the death of Dr. E. R. Hun; adopted.

Dr. Gray presented some extended resolutions on asylum reforms. Upon motion of Dr. Hammond, these resolutions were not acted upon until later in the day.

The first paper of the afternoon was read by Dr. **G. N. Hammond**, entitled

CONTRIBUTION TO JACKSONIAN EPILEPSY.

The histories of three cases of so-called Jacksonian epilepsy were given. Attention was called to the fact that Dr. Jackson did not consider loss of consciousness to be an essential element of an epileptic paroxysm, but that he had described a variety of the disease consisting of sensory and motor disturbances, but in which consciousness remained unimpaired. Dr. Hammond regarded this disorder as being epileptoid and not true epilepsy, and, in fact, had no tendency to pass into true epilepsy.

Two of the patients referred to in the paper were presented to the Association. One of these was a Hungarian, who had attacks of tonic rigidity of the muscles of the neck, sometimes of one side, sometimes of the other, and again in the posterior region. There were two kinds of auræ: one in which he saw bright lights of all colors, accompanied by a sensation of distress in the epigastrium; the other, in which the left ear became "fiery hot." The epileptic zone was seated in the scalp, and the slightest touch on this portion of the head was sufficient to cause an attack; and even approaching him with the hand, as if about to touch his head, was productive of a like result.

Dr. **Hammond**, Senior, in response to the inquiry of Dr. Gray, stated that he had never seen a case so exaggerated as this, nor one where the zone was so extensive. He thought, in those attacks which came on from peripheral irritation, that the patients did not lose consciousness; and it was because of this one point why he thought such cases were not epilepsy. In the case which his son presented, the patient could see and think at the height of the paroxysm.

Dr. **Miles** recalled the case of a boy who, when he began to cough, if it was continued, twisted himself over, cut several regular steps, and then fell down.

Dr. **Kinnicutt** said he had seen and examined a case similar to the one presented by Dr. Hammond. It was found that the slightest touch of the zone in the scalp produced a paroxysm, which consisted of the elevation of the arm and the muscles of the trunk, but not of the lower extremities. This was usually accompanied by one cry as the arms went up. The hair could not be brushed without this occurring.

Dr. **Jewell** remarked that an epilepsy, for him, included just two things: loss of consciousness followed, or usually followed, by more or less muscular action. There might be other symptoms, but these were the most characteristic. He thought we ought to be very careful in the use of the term "epilepsy," especially before patients.

Dr. Beard believed that in epilepsy we must have loss of consciousness and convulsive movements.

Dr. Hammond, Senior, thought if Dr. Jewell included in his definition sensory disturbances as well as motor, he would have the best definition possible. Making this change, the definition of epilepsy would read : "An abnormal sensory or motor disturbance, attended with unconsciousness."

Dr. James J. Putnam, of Boston, reported a case of

ACUTE MUSCULAR ATROPHY WITHOUT LESION OF THE CORD.

The Dr. believed the case to be one of disseminated neuritis. The pain, loss of electrical reaction, and rapid muscular wasting were the prominent features of the case.

After this, **Dr. Putnam** read an interesting paper on

NUMBNESS.

Within the past ten years there had come under his notice a large number of cases, such as he had not remembered to have seen described anywhere in detail, though they were often the subject of brief reference. Differing in minor respects, these cases presented, as a common symptom, disturbance of the subjective sensibility of the skin, giving rise to what was broadly known as numbness, recurring periodically, coming on especially at night or very early in the morning, and affecting one or both hands, either alone or in company with the arm, the leg, or rarely the whole body. This numbness was very often excessively intense, so as to amount to severe pain, sometimes being associated with pain of a more or less neuralgic character, especially in the arms. In treatment he had used galvanism, phosphorus, strychnia, bromides, cannabis indica, nitrite of amyl, and a few other remedies.

Dr. Miles referred to the history of a case he had published, where the extremest atrophy existed, but there was no absolute paralysis, the loss of power being due to a loss of muscular substance. He thought it impossible, at first, to excite contraction of the muscles, but the application of electricity was continued, and complete recovery took place.

Dr. Jewell inquired what Dr. Putnam thought of atrophies arising without any disease whatever of the nervous system.

Dr. Putnam replied that he had great respect for the opinion that the disease was of primary myopathic origin.

Dr. Jewell said he had seen one or two cases during the past year, and one of them he thought must have been of that origin. It seemed to be purely a local disease of the muscles ; that is, it began in the muscles, without any reference to the motor nerve ; he did not say independently of the *vaso-motor* nerve.

Dr. Hammond remarked that he had seen several of these cases, but he had never seen them lead to any bad results. All of his cases had recovered under the galvanic current.

Dr. Miles referred to a case he now had, where the numbness was confined entirely to the hand. There was no pallor, but rather the contrary.

Dr. Seguin stated that he had been seeing such cases ever since he became interested in nervous diseases. Most were cases of numbness in the hands and forearm ; to a certain extent, in the arms. He thought the affection was bilateral in all of his cases ; not in one of his cases were there evidences of organic disease ; no anæsthesia, no paralysis. Treatment had been rather unsuccessful. Temporary relief had been obtained by applications of hot water. The best results had been from a general tonic course of treatment. He was rather inclined to think that these cases depended upon some slight change in the posterior columns of the cord. He would not admit the vaso-motor theory.

Dr. Jewell referred to a class of cases having more or less persistent numbness, without any vaso-motor trouble whatever, and occurring more frequently in women than in men, and which were worse in the latter part of the day if the patients did not lie upon their back. His hypothesis was that these were cases of spinal exhaustion. The numbness was an expression of the wearing out and the gradual increased passive dilatation of the blood-vessels, which sometimes was worse and at other times better, according as the numbness was more or less profuse. Rest was exceedingly important in the cure of these cases.

Dr. Putnam remarked that in five or six of his patients there were distinct vaso-motor disturbances. The disturbance was of course connected with the central circulation.

Dr. Hammond's theory as to why washerwomen were so subject to numbness of the hands was that those members were placed in hot and cold water alternately.

Dr. Jewell said that not even the majority of his cases were washerwomen. He supposed that through that zone of the cord the circulatory disturbances might spread from one region to the other, and that from the way these attacks came on we must have some sort of shifting cause. Effects told something of the nature of the cause, and he knew of nothing that would produce this coming and going of the loss of sensibility unless it was a disturbance of the circulation.

Dr. Hammond said there was such a thing as exhaustion of the cord ; but you did not have the condition of hyperæmia in exhaustion of the cord, nor did you have numbness.

There being no further discussion of Dr. Putnam's paper, **Dr. W. R. Birdsall**, of New York, reported a case of

REMARKABLE TUMOR OF THE ENCEPHALON.

Dr. Seguin said he had seen the case several times, and delivered a clinical lecture upon it. The patient presented a partial left hemiplegia of the leg chiefly; but she had right facial paralysis and exquisitely marked choked disk. The diagnosis made before the class was that she had a cerebral tumor located in the anterior half of the pons varolii upon the right side. He was surprised to find at the post-mortem no lesion in this region, but an enormous tumor in the medulla oblongata. It was a case of common facial palsy, but did not seem to be Bell's palsy.

The Secretary read a letter from Dr. William A. Hammond, of New York, offering a prize of $500 to the American Neurological Association, for the best essay on "The Function of the Optic Thalamus," to be presented in 1882. The prize was open to neurologists in all parts of the world.

Upon motion, the Association adjourned.

Third Day—Evening Session.

The Association was called to order at 8.30 P.M.

In accordance with the motion of Dr. Hammond, the resolutions offered by Dr. Gray were taken into consideration, and after some discussion were adopted. An additional resolution was adopted, providing for the printing and sending of these resolutions to American and European journals.

Dr. E. C. Spitzka read by title a paper on

THE HOMOLOGIES OF THE MESENCEPHALON IN THE VERTEBRATE SERIES, WITH THE DESCRIPTION OF A NEW MESENCEPHALIC GANGLION.

Dr. Spitzka then made a verbal statement in regard to a hysterical case. The patient had been treated for acute miliary tuberculosis, and had remarkable dyspnœic movements. She also had what is usually called vicarious menstrual vomiting of large quantities of blood from the stomach, without menstrual flow. Afterward Dr. Spitzka made a careful examination of the case and obtained a full history.

All sorts of diagnosis had been made of heart and lung lesions, as well as hysteria. Dr. Spitzka excluded thoracic complaints, but thought she might be hysterical, and believed that all her symptoms were due to gastric ulcer. She not only had pain after eating, but always had it at the same point; it was aggravated with every deep inspiratory movement. Under treatment the stomach regained its normal condition, but the patient would not take care of herself; she was now in a hysterical state. The point which Dr. Spitzka wished to bring out was, that he thought there could be little doubt as to the origin of the blood, which was not hæmoptysis, but hæmatemesis.

DIAGNOSTIC SIGNIFICANCE OF A DILATED AND MOBILE PUPIL IN EPILEPSY.

A paper upon this subject was read by **Dr. Landon Carter Gray**, of Brooklyn.

A symptom which was of great importance in doubtful cases was a dilated and mobile pupil. He had examined forty-nine patients in all, and in every instance, except four, found that the pupil possessed this characteristic symptom. By means of this symptom he had been enabled to make a diagnosis in several instances where the history was uncertain, or he knew nothing of it. He was, therefore, almost willing to affirm that this symptom was pathognomonic, and he committed it to the criticism of the profession in the hope that it might prove of as extended and certain application as he anticipated.

Dr. Spitzka said that while he attached great importance to the dilated pupil, he had found cases where it was absent; those cases occurring late in life in which there was a peculiar pupil, something like that of general epileptics.

Dr. Cross remarked that, although he had not made a note of the conditions of the pupil in studying the ophthalmoscopic appearance of the retina in epilepsy, he remembered that in a large number of cases there was dilatation of the pupil.

Dr. Gray remarked that his point was that the pupils were dilated and mobile.

Dr. Hammond had not noticed the point insisted on by Dr. Gray.

Dr. Spitzka stated that in alcoholic epileptics the pupil was normally, or more than normally contracted. He asked for Dr. Kiernan's observation upon cases of alcoholic epilepsy.

Dr. Kiernan remarked that in these cases he must confess that he had noticed the symptom of a largely dilated and mobile pupil. The same had been noticed in forms of insanity associated with masturbation. In about twenty per cent. of the cases observed by him, this symptom was present.

Dr. Kinnicutt had recently seen two cases of melancholia in children where the etiological factor was supposed to be masturbation, and in both cases the pupils were largely dilated and mobile. Within the past year he had seen seven or eight such cases.

The papers of Dr. Miles of Baltimore, Schmidt of New Orleans, Spitzka of New York, Bannister of Chicago, and Lombard of England were read by title.

Drs. Miles, Seguin and Jewell were appointed a committee to decide in regard to the merits of the papers presented for the Hammond prize.

Upon motion the Association adjourned to meet for its next annual session in New York city, upon the regularly appointed day.

Correspondence.

HYSTERO-EPILEPSY—ITS HISTORY, Etc.

To the Editor of The Medical Record.

Dear Sir:—I have no doubt that many an old subscriber, who, at home, has been under a grateful sense of obligation to the Record for much or all that is new and interesting, medically speaking, feels when abroad, and in the presence of fresh medical scenes, that it would be only a simple debt of loyal repayment to contribute, in turn, his mite to its pages.

But, easy as it is to reason thus, it is more difficult by far, in the presence of the many changing scenes of a foreign city, to put the thought into practice; however, with the Record's permission, I will attempt to discharge my debt, from time to time, in the form of a few scattered notes, principally upon certain subjects about which the medical world has not yet formed fixed opinions, trusting that for this reason my notes may not prove altogether uninteresting.

Of the many novel things that reached us of late in America, none were more novel, nor received, in some respects, with more scepticism, than the reports, both verbal and printed, that came to us of the doings of Professor Charcot, at the famous Hospital of Salpêtrière, in regard to hystero-epilepsy. True, hystero-epilepsy itself, thanks to the indefatigable and acute study of Charcot, has taken its place in medical literature as a distinct and now easily recognizable entity, and we have all become familiar with the well-defined symptom picture of the complete hemianæsthesia not only of general sensibility, but also of the special senses (achromotopsia, etc.), the hyperæsthesia of the ovary (ovaria), the possible contractures, and the now classical seizures, or fits.

But above and beyond this simple statement, there was much not so easy to understand, and not so easy to verify. I refer particularly to the effects stated to have been brought about by the use of metals and magnets, reviving, in the latter instance, the curious theories and statements already advanced by Burq, under the name of metallotherapy. The wonder lay, not in the results of metallo-therapy, but in the fact that it was seemingly endorsed by the great name of Charcot. And, as regards America, I do not know that metallo-therapeutics, so-called, or any of its primary and essential phenomena even, has ever been verified, though in a single instance, at least, it has been denied on the basis of an apparently fair trial.

If we add to magnets and metallo-therapy the many other curious phenomena presented by the hystero-epileptics at Salpêtrière, and now being subjected to patient study, though not yet presented in printed form to the profession—if we add, namely, the hypnotism, the mesmerism, the catalepsy, the somnambulism, and the effects of static electricity, as well as magnets, in these cases, we have opened out to us a wide field for interesting observation. We must not forget, moreover, that we are at a head-quarter of "cerebral localization," and that some points on this subject may fall in by the way.

I confess, under the circumstances, that I approached Salpêtrière like a pilgrim to a Mecca—with not all a pilgrim's faith, perhaps—but regarding it, nevertheless, as a goal much to be desired. And I shall start at once by taking the readers of the RECORD into my completest confidence, promising to observe for us both simply the facts in the case, according as they shall present themselves. *Nous verrons ce que nous verrons.*

But first, a few words about Charcot and the Salpêtrière.

Provided with agreeable letters of introduction, I called, soon after my arrival in Paris, upon Professor Charcot. Few names are more familiar to American readers of foreign literature, than Charcot's, and few more justly celebrated in his own country than his. As a specialist in diseases of the nervous system, it scarcely needs be said that that he is among the foremost. It may not be so well known that, not contented with a single specialty, he ranges widely over other branches of medicine; for instance, he is now delivering a course of lectures upon diseases of the kidneys.

Charcot lives on the banks of the Seine, in a fine old residence. Our card is carried in, and while waiting, we can scarcely fail to note our surroundings. It is evident at once on every hand that the occupant's fervor for medicine has not been inconsistent with the gratification of a strongly expressed taste for art; that wealth, while affording freer scope for following more in detail special directions of study, has found equal expression in the outward evidences of comfort and luxury. I merely note, in passing, a single room furnished in Japanese style in bamboo and drapery, whose walls were covered by placques, designed and painted by Charcot himself, from scenes at his country place and elsewhere.

We have not, however, long to wait. The potent title of Dr. on our card gains us immediate entrance. We enter the library, filled from floor to ceiling with attractive rows of books. A bust of their owner, already familiar to American neurologists by his photograph, stands in view. The original of the bust now quickly appears from a consulting-room and makes us welcome.

Charcot's personal appearance is striking. His face once seen is not easily forgotten; it is, at the same time, intellectual and spirituelle.

So much for details not uninteresting, I am sure, to the many readers of Charcot's works. My greeting, thanks to letters from friends at home, was a most agreeable one, and I was at once invited to avail myself, in the fullest manner, of the teachings at the clinic and in the wards of the hospital. The next morning I was early on my way to Salpêtrière. But why called Salpêtrière, or as the word translated signifies, saltpetre works? In the answer we may find a bit of interesting medical history, gleaned with some trouble from various sources, for there appears to be no annual "report" to refer to as with us. Such reports here are made to the director of public charities, but not printed.

In 1656, Louis XIV. established under one direction all the hospitals of Paris. Some buildings formerly used as saltpetre works were appropriated to public use and transformed into dormitories. At this date even, Salpêtèrie, as it now had become christened, contained nearly a thousand pauper women and children. In 1684 certain other buildings were erected and used as prisons for females, and finally the insane also in great numbers were confined here, until at last the place became an enormous bedlam. By the end of the eighteenth century it was the largest hospital in Europe. Tenon writes that he saw there at one time as many as 8,000 inmates, consisting of old and decrepit women, dissolute and criminal women in the prisons, pauper children, furious maniacs, imbeciles, epileptics, paralytics, the blind, cripples, and those afflicted with scurvy and a variety of incurable diseases.

This was the Salpêtrière of the end of the eighteenth century—the Salpêtrière which Pinel found when he was appointed physician-in-chief to it, as well as to Bicêtre, the corresponding institution for the custody of males.

We may judge of the condition of the insane at this Bedlam by a few words which I will translate from a good authority: "At Salpêtrière there were cells called the lower cells, situated more than fifteen feet below the new cells." These are described as follows by M. Desportes, administrator of hospitals, writing in 1822: "The lower cells of Salpêtrière differ in no respect from those of which I have just spoken. Built one against the other they receive neither light nor air except by the door; but that which renders them still more calamitous and often fatal is the fact that in winter, when the waters of the Seine rise, these cells, situated at the level of the sewers, become not alone very much more unhealthy, but furthermore a place of refuge for throngs of immense rats, which attack in the night the miserable occupants and bite and gnaw them whenever they can get at them. At the morning visit certain of these insane are found whose feet, hands, and face are torn by bites often dangerous, and from which several have died." *

But there is nothing in the present of Salpêtrière to suggest such a hideous past. Once within its gates, one has entered an enclosure of eighty acres, containing forty-five blocks of substantial buildings. These buildings are arranged in squares, enclosing within their general ground-plan a dozen or more large rectangular courts which, in fact, are so many beautiful gardens planted with trees in long arched colonnades and adorned with multitudes of well-tended flower beds. As now organized, the inmates are divided into three classes, the insane, epileptics and hysterics, and old women. There is also an infirmary for out patients, consisting of two services, a surgical and a medical. It is with the latter as well as with the epileptic and hysterical wards, both under the charge of Prof. Charcot, with which we are for the present chiefly interested. As I passed by the kitchen department breakfast for about 5,000 people was being cooked and served. In the various gardens, sitting on benches beneath the trees, or chatting in groups beneath the same shade, or hobbling along with canes, were hundreds of old women who now comprise the largest portion of the inmates of this great almshouse.

But it is not alone the vast extent and number of its buildings, the multitude of poor which it houses, feeds, and treats medically, that has given this institution its world-wide fame, but it is the vast services which humanity has received from it through the labors of faithful and able physicians. From its walls first went forth to France the principle of a humane treatment of the insane as well as of a rational treatment of insanity.

---

* Étude sur les hôpitaux, par M. Armand Husson, Paris, 1862, p. 286.

It was here in this very corridor itself, which we are traversing to reach the door of Charcot's clinic—a corridor and a scene familiar to many by the picture representing the event—that Pinel first cast off the chains from the insane, and taught not alone humanity to his times, but went farther, and instituted the first instruction upon mental disease ever given in France. True, his pupils were few, his instructions theoretical; but it was a beginning. And at this same hospital Esquirol, friend and colleague of Pinel, took the next great step and established a clinic for the study of mental disease, at which (yearly, from 1817 to 1826) he laid down the first sound doctrines of mental disease. It was Esquirol who, with Bichat, established in France the somatic rather than the psychic theory of insanity, who taught that insanity was a disease of the body itself, not of the spirit, and that it was to be studied from the standpoint of physiology and pathology, rather than that of metaphysics and theology. Pinel's work was humanitarian; Esquirol reduced insanity to a science. Pinel threw open the doors to reform by removing the chains from the insane; Esquirol took the emancipated in hand and studied their disease on a scientific basis.

But we must not forget that this is a morning visit and thus dwell too long in reveries of the past. Charcot's clinic, to come at once to the subject in hand, is very perfectly appointed. We may take a hasty glance at the rooms before the clinic begins.

Leaving the antechamber, where patients and attendant are waiting, we enter the reception-room, where they are received and their cases examined, recorded, and treated. This reception-room forms but one of four rooms devoted to the same purposes, though in different directions of study. The second and largest is used for treatment by electricity; the third is for chemical examinations, and the fourth is used for photography.

The reception-room itself contains much that is suggestive and interesting. Its walls are covered with old prints representing biblical occurrences, such as St. Paul and St. Peter healing the sick, scenes in demonology and witchcraft, miraculous cures by saints, saints in ecstasy, the contortions of *convulsionaires* in the middle ages, etc., etc., down to "miraculous" cures recorded in the present. Here, in particular, is a picture of a patient with what is evidently, from the description given beneath, an hysterical contracture, being carried to the tomb of St. Medard to be cured. In the accompanying picture the cure has been effected, and we see the patient walking about with perfect use of her limbs. Charcot seems to delight in collecting these prints, for can he not confront them in his own clinic with equal wonders, with equally persistent and hideous deformities, relieved by no miracle, by no appeal to a saint, but cured simply in accordance with modern scientific knowledge? To the physician of to-day the sudden relief of hysterical deformities is no longer a miracle. On the walls of this room we seem to be intentionally brought face to face with the whole past history of nervous diseases in some of its strangest and most unique aspects.

But let us leave this room and enter the second—that devoted principally to electrical apparatus and treatment; and here we shall find the surroundings and the paraphernalia of a scientific and intelligent present. Here, too, are pictures on the walls, but they are pictures—photographs and crayons—taken from life, and from patients in this very hospital, in stages of fury, of contortion, of passional ecstasy as vivid and as real as it is possible to imagine any saint or *convulsionaire* of the past may have exhibited. Here, in this room, are patients by the dozen whose hysterical contractures yielded, as we shall see, to the exorcisms of modern science as speedily as did any who were led to the tomb of St. Medard. Here are hysterical girls who, in their hypnotized and mesmeric states, see visions as beatific as did ever saint of old or modern virgin of Lourdes, whither now flock thousands of believing pilgrims. But science takes a step in advance of superstition; it may originate at will these very visions in the mind of the subject, now called simply a patient; it may give not only the details of the vision, but also the very tone and coloring of it; and the things seen shall afterward be faithfully repeated, with an earnestness and a vividness which leave no doubt in the mind of the hearer of the reality of the hallucination created.

Science, too, may create these contractures and bring on these contortions and convulsions at will, as well as relieve those that have occurred spontaneously and those that have been induced (artificial hysterical contractures). What superstition calls a miracle, science creates at the physician's bidding. In this room, then, we see the modern "possessed." Charcot has found them out, has studied their disease and made it intelligible—has named it Hystero-Epilepsy. Indeed to him the world owes a great debt of gratitude that he has made these cases clear, and thus not only made their proper treatment understood, but gained for the poor hysterical a charity not formerly so freely accorded them. Medicine is thankful for light thrown upon the protean form of hysteria. Science, too, is thankful that in denying a miracle it can do so on a basis of demonstration.

But, besides pictures and patients, here are elaborate galvanic, faradic, and static electrical machines; there also are magnets, metals, colored disks for testing hysterical amblyopia, and various appliances for registering symptoms, whose enumeration will too much task the reader. Indeed it is time to remember that details, vivid enough upon the spot, may grow dim in interest by distance. In my next I will speak only of the daily transactions at the clinic, excusing this excursion into the past by the hope that the clinic's present may appear more real by reason of its historical setting.

Very truly yours,
William J. Morton, M.D.

Paris, July 22, 1880.

PHYSICIAN AND PHARMACIST.

To the Editor of The Medical Record.

Sir:—As the physician has had his audience it may not be improper that the druggist should have a hearing on the subject of *incompetency*, as alluded to in the Record of July 3, by * * * *.

Now, while we do not wish to offer an apology for the man who will not arise in the dead of night to prepare a very simple cough remedy, or the man who cannot read a prescription, whether the spelling, writing, or abbreviations be according to the rules of art or not; yet, we do state that far more mistakes are made by the writers of formulæ than by the compounders.

It is not every man who writes his name with an attachment of M.D. who can, or will, *or does* write his prescription so that a man with a fair average amount of brain could swear that it was correct—as the M.D. intended; nor is it very unusual that the doctor takes from his pocket some formula-book and writes from it, and if he did examine he would be unable to tell if it was or was not correct. Then the physician sometimes writes ʒ's for ℥'s or other mistakes in putting incompatables into the same bottle, and expects his druggist, "*if he knows anything*" to rectify *those little things.*" For instance, I copy from my prescription book, *verbatim et literatim :*

℞. "For Mrs S——
Quinia sulph .... gr xv
Morph. sulph. .... ʒ iss
Ferri carb .... gr iij
Ft chts No ix
Sig One three times a day and oftener if necessary to quiet pain."

and this bore the signature of a regular graduate of one of the first colleges in the land.

And, taking the correspondent * * * * argument, we must be our own doctor and thus relieve the physician of any further complaints.

Now, in concluding this I will say, I have written recipes for twenty-five years, and a considerable portion of that time have been also connected with the dispensing department of a drug store, and I have found quite as much "incompetency" in the practice of medicine as in the dispensing of medicine.

C. T. Armstrong.

Corunna, Mich.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 15 *to August* 21, 1880.

McKee, J. C., Major and Surgeon. Granted leave of absence for one year, on Surgeon's certificate of disability. S. O. 177, A. G. O., August 19, 1880.

Happersett, J. C. G., Major and Surgeon. At the expiration of his present leave of absence, to report to the Commanding Officer, Ft. Ringgold, Tex., for duty as Post Surgeon. S. O. 161, Dept. of Texas, August 10, 1880.

Taylor, M. K., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon at Ft. Concho, Texas. S. O. 161, C. S., Dept. of Texas.

O'Reilly, R. M., Capt. and Asst. Surgeon. His leave of absence, on account of sickness, extended four months on Surgeon's certificate of disability. Relieved from duty in Dept. of the South, and at expiration of his present leave of absence to report by letter to the Surgeon-General. S. O. 174, A. G. O., August 16, 1880.

Moseley, E. B., Capt. and Asst. Surgeon. His leave of absence extended ten days, with permission to apply for a further extension of two months. S. O. 75, Dept. of the Platte, August 17, 1880.

Carter, W. F., 1st Lieut. and Asst. Surgeon. When relieved by Asst. Surgeon Taylor, to report to Commanding Officer, Post of San Diego, Tex., for duty as Post Surgeon. S. O. 161, C. S., Dept. of Texas.

An Act entitled "*An act to regulate the licensing of physicians and surgeons.*"—Chapter 513. Passed May 29, 1880; three-fifths being present.

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

Section 1. A person shall not practise physic or surgery within the State unless he is twenty-one years of age, and either has been heretofore authorized so to do, pursuant to the laws in force at the time of his authorization, or is hereafter authorized so to do as prescribed by chapter seven hundred and forty-six of the laws of eighteen hundred and seventy-two, or by subsequent sections of this act.

§ 2. Every person now lawfully engaged in the practice of physic and surgery within the State shall, on or before the first day of October, eighteen hundred and eighty, and every person hereafter duly authorized to practise physic and surgery shall, before commencing to practise, register, in the clerk's office of the county where he is practising or intends to commence the practice of physic and surgery, in a book to be kept by said clerk, his name, residence, and place of birth, together with his authority for so practising physic and surgery as prescribed in this act. The person so registering shall subscribe and verify by oath or affirmation, before a person duly qualified to administer oaths under the laws of the State, an affidavit containing such facts, and whether such authority is by diploma or license, and the date of the same and by whom granted, which, if wilfully false, shall subject the affiant to conviction and punishment for perjury. The county clerk to receive a fee of twenty-five cents for such registration, to be paid by the person so registering.

§ 3. A person who violates either of the two preceding sections of this act, or who shall practise physic or surgery under cover of a diploma illegally obtained, shall be deemed to be guilty of a misdemeanor, and on conviction shall be punished by a fine of not less than fifty dollars nor more than two hundred dollars for the first offence, and for each subsequent offence by a fine of not less than one hundred dollars nor more than five hundred dollars, or by imprisonment for not less than thirty days nor more than ninety days, or both. The fine, when collected, shall be paid, the one-half to the person or corporation making the complaint, the other half into the county treasury.

§ 4. A person coming to the State from without the State may be licensed to practise physic or surgery, or either, within the State, in the following manner: If he has a diploma conferring upon him the degree of doctor of medicine, issued by an incorporated university, medical college, or medical school without the State, he shall exhibit the same to the faculty of some incorporated medical college or medical school of this State, with satisfactory evidence of his good moral character, and such other evidence, if any, of his qualifications as a physician or surgeon, as said faculty may require. If his diploma and qualifications are approved by them, then they shall endorse said diploma, which shall make it for the purpose of his license to practice medicine and surgery within this State the same as if issued by them. The applicant shall pay to the dean of said faculty the sum of twenty dollars for such examination and endorsement. This endorsed diploma shall authorize him to practise physic and surgery within the State upon his complying with the provisions of section two of this act.

§ 5. The degree of doctor of medicine, lawfully conferred by any incorporated medical college or university in this State, shall be a license to practise physic and surgery in the State after the person to whom it is granted shall have complied with section two of this act.

The Foramina of Monro—Correction.—In our abstract of Dr. Wilder's paper in the Medical Record for August 7th, the word "*radial,*" near the top of page 157, should have been "*ventral.*" In the last paragraph, "*tuberculum anlæ*" should be "*crista fornicis.*" We understand that Prof. Wilder will present a paper on the Foramina of Monro at the coming meeting at the American Association for Advancement of Science, in Boston, and that some historical questions connected with the subject are discussed in the last number of the *Boston Medical and Surgical Journal.*

Dr. Wellington N. Campbell, of this city, died of phthisis, in Burlington, Canada. He graduated at Bellevue Hospital Medical College, was afterward Ambulance Surgeon to the hospital, House Physician to Ninety-ninth Street Hospital, served six years at the New York Dispensary, and three years at the Northern Dispensary.

The Report of the American Veterinary Hospital for the year ending February 25, 1880, shows that we have in this city a well organized and very useful institution for veterinary study. The hospital is maintained in connection with the American Veterinary College and is officered by four veterinary surgeons, of whom Dr. S. Liautard is chief. During the past year 2,442 patients were treated, 1,880 of these were cured, 11 were discharged because affected with contagious diseases or incurable, and 24 died. Two hundred and sixty-six operations were performed, in many cases while the patient was anæsthetized.

The records of this as well as of other similar hospitals and colleges show that veterinary science in this country is advancing every year.

A Somewhat Crowded Profession.—In the Sherley Will case before the Louisville Court the other day, in reviewing the medical testimony, Colonel McKay, one of the counsel for the will, remarked upon the number of doctors in the world, and said that down "in his country, between the hills and the river, they are so thick that two had to ride one horse; and that, a flat-boat having been stranded in the river one night, the next morning three doctors' signs were hanging out from its sides."—*Louisville Medical News.*

The Epidemic at North Adams, Mass., to which reference was made some weeks ago, has been traced to the water drunk by the inhabitants of the town. A stream flows through the place, and it was found that all the cases of disease occurred in families who got their water below a certain pond on that stream. The water of this pond is shallow and the bottom covered with a mass of decaying vegetable matter. Some atmospheric influence, it is said, has also to be called in, in order to fully account for all the cases.

A New Cause of Death.—A Philadelphia "doctor" recently signed a certificate of death from "collary fantum." He is a colored graduate of a bogus school, and the courts have shown a disposition to investigate his right to practise. This is the second or third case that has attracted attention within a few weeks, of ignorant men professing to be skilled physicians.

Is Buchanan Dead?—The city of Philadelphia has been unable to determine whether Dr. Buchanan, of unsavory reputation, is alive or dead. He was to appear for trial on the charge of issuing bogus diplomas, and using the mails for that purpose. Just before the time for his appearance at court, a man resembling the professor was seen to jump from a ferry-boat into the Delaware. As it was night it was scarcely possible to tell whether he drowned or swam to a place of safety. The court has been petitioned not to forfeit his bail, since it is impossible for the bondsmen to produce the suicide. The river has been dragged and no cadaver found. The prosecution holds that it is a ruse of the wily doctor to escape conviction, for, by latest accounts, he has reached Canada in disguise.

The Atlantic City Accident.—Twenty-one victims of the accident on the Atlantic City branch of the West Jersey Railroad, have died. Many of them were treated at the Pennsylvania Hospital. Those received at that institution were burned about the hands, face, and legs. The women were severely burned up to the thighs, but the men, as a rule, escaped, on account of the difference in dress. The treatment consisted of carbolized oxide of zinc ointment locally, with anodynes and stimulants internally. Death, in most instances, occurred from shock.

Regulating Prostitution.—The new Parliament of England has appointed a committee to continue the inquiry into the workings of the Contagious Diseases Acts.

Honorary Degrees at the British Medical Association.—On August 11, 1880, a meeting was held for the purpose of conferring honorary LL.D. degrees upon some of the most distinguished members of the British Medical Association. The degree was granted on June 10th of last term, and fourteen gentlemen were selected. Of these, Dr. Paul Broca, Prof. of Surgical Pathology in the Faculty of Medicine, Paris, has since died, and Dr. Chauveau, of Lyons, was unavoidably absent. All the others were present and were admitted. Their names are as follows: Dr. C. E. Brown-Séquard, of Paris; Dr. F. C. Donders, of Utrecht; Dr. S. D. Gross, of Philadelphia; Sir Wm. Jenner, Sir Wm. Gull, and Sir Geo. Burrows, of London; Rev. S. Haughton, M.D., F.R.S., of Dublin; Mr. Wm. Bowman and Mr. Joseph Lister, of London; Mr. Dennis O'Connor, of Cork; and Mr. John Simon and Mr. Andrew Wood. The public orator was Mr. J. E. Sandys, of St. John's College. The Vice-Chancellor afterward entertained the newly created doctors and a distinguished company at luncheon at Corpus Christi College.

The Vital Statistics of European cities for 1879, show that Christiania had the lowest death-rate, viz.: 17·5 per 1,000; and St. Petersburg the highest, 40 per 1,000.

An Epidemic of Pernicious Anæmia, which has recently been observed among the miners of the St. Gothard tunnel, is attributed, by Dr. Perroncito, to the presence of certain parasites in the intestines. Three different kinds of worms have been found in the dejections. One of these, an anchylostoma, is called Dochimus duodenalis; the others are varieties of anguillula.

Non-restraint in the Treatment of the Insane.—Dr. Rutherford, of the Parochial Asylum, at Woodilee, Scotland, states in his recent annual report that, mainly through fully occupying the patients, and thereby counteracting the tendency to manifestation of their insane ideas, it has been found practicable to carry out the open-door system of treatment. All the doors of the asylum open with ordinary handles, and only the chief attendants are in possession of a key. Dr. R. believes that by the diminution of apparent restrictions upon liberty, greater quietness and contentment are secured, which have the effect of promoting recovery.

A New Ophthalmological Society has been organized in London, and calls itself "The Ophthalmological Society of the United Kingdom." It at present embraces eighteen members, most of whom are London surgeons.

A Novel Treatment for Dysentery.—M. Verneuil recently reported the case of a wood-cutter, who had for several years suffered from dysentery, with incontinence of fecal matters. To remedy this he was in the habit of introducing into the bowel a plug of wood wrapped in linen cloth, of which the ends were allowed to protrude. On one occasion, however, having forgotten these appliances, he made use of a branch of poplar, cut roughly conical with an axe. Whilst at work this suddenly slipped up into the rectum, out of reach. M. Verneuil subsequently performed gastrotomy and rectotomy in order to get it out, which was done successfully.

Progress in the Treatment of the Insane in England.—A bill has been introduced into the House of Commons, which will initiate some very radical changes in the care of the insane. It provides a plan by which private asylums shall gradually be put under public control, and by which medical treatment shall become a more prominent feature in these institutions. There has been considerable complaint of late that English private asylums are too often only commercial ventures, in which the medical element is subordinate. They are accused of being elegant retreats rather than hospitals.

Treatment of Lung Cavities by Paracentesis.—A case has recently been reported by Dr. R. D. Powell and Mr. R. W. Lyell, of London, in which a basic cavity in the lung was treated by paracentesis. Some immediate improvement was gained, but the patient died in about seven weeks. The operators considered that paracentesis would often be a justifiable operation in chronic basic cavities. They did not advise it in apex cavities, however—an opinion which is counter to that of Dr. Pepper, who has been experimenting in this direction.

The St. Louis Medical College announces its adoption of the three-year graded course.

The Influence of the Excess of Alcohol on the Death-rate.—Dr. Norman Kerr, in a paper read before the Section in Medicine of the British Medical Association, gave as an approximate estimate of the mortality from alcoholic excess, 120,000 deaths; 40,500 resulting from personal intemperance, 79,500 from starvation, disease, accident, or violence arising from the intemperance of persons other than the killed.

Medical Education in the West.—It is, perhaps, an indication of better times, when medical colleges find it for their interest to advertise themselves by announcing an extra long and severe curriculum. The only possible excuse, indeed, for the organization of a new medical college is to supply the demands of a higher medical education. This excuse is therefore seized upon. The last instance is that of the St. Paul Medical College, which announces that it will open with a full graded course of four years. Four years' study will be required as a requisite to graduation; and there are preliminary and annual examinations.

A Case of Superfœtation is reported in the *Chicago Medical Journal and Examiner*, by Dr. D. A. Walden. A primipara, aged twenty, married ten months, was taken with labor-pains April 18th, and next day was delivered of a full-term child. The patient did well until two days later. On that day, while using the vessel, there passed from her a complete unruptured sac, containing a male fœtus and placenta about four months old. The woman made a rapid recovery. She stated that she had menstruated for three or four months after she was aware of her pregnancy. There were no signs of a double uterus. In a somewhat similar case, related by Playfair, menstruation was kept up during the whole period of pregnancy.

The Compressed Air Bath is a therapeutic measure which is gaining some advocates in this country, as well as abroad. There are a few physicians in this city who use it, and *The St. Louis Courier* states that it is being tried in St. Louis. Its special use is in cases of asthma, emphysema, and chronic bronchitis. A new application of the method, however, is in the treatment of obesity. Two cases have been reported by Dr. Charrier in *L'Union médicale;* in one the weight was reduced from 232 to 210 pounds in 25 days.

Suspension of the Heart's Action.—In the *Louisville Medical News*, Dr. J. A. Long reports a case of a negro whom he had been treating for congestion of the brain. On the first day of attendance the patient was delirious; his pulse was 104, and lost one beat in eight; the day following it lost one beat in six, next day one in three. On this day, while standing by the patient, the breathing and heart-beats suddenly stopped completely, and the man appeared completely dead. He was so pronounced by the doctor. About five minutes later, however, he began to breathe again; the heart's action returned, and he lived twelve hours longer.

The International Medical Congress meets in London in August, 1881. Arrangements for the occasion are already under way. Burlington House has been secured for the meetings of the congress. The executive committee has nominated Sir Wm. Gull, Mr. Erichsen, and Dr. Matthews Duncan, as presidents of the medical, surgical, and obstetrical sections respectively.

Sanitary and Medical Matters in Japan.—In 1873 a sanitary bureau was created by the government of Japan. Its first report, covering the two years from 1875 to 1877, has just been published. The document gives a very clear idea of the condition of sanitary and medical matters in Japan, and it shows the difficulties which the bureau has had to encounter in its efforts to improve the status of medicine and hygiene. The bureau was empowered to regulate the practice of medicine and of pharmacy by prescribing courses of studies and the examination tests. It was given control over the sale of drugs, patent medicines, poisons, etc., and it possesses the other ordinary duties of health boards in the matter of registration of diseases, quarantine, etc. Not all of these things could be attempted at first, however, and even now a thorough sanitary organization is far from existing. The board has certainly acted in a wise and intelligent manner, however, and has made all the progress possible. There is still a vast degree of ignorance and superstition among the lower classes, as may be inferred from the quality of the medical services which they call for. There are in Japan over 31,268 physicians, or about 1 to every 1,100 inhabitants. Of these, 66 per cent. follow the Chinese system, 13 per cent. the "mixed system," and 21 per cent. the "Western" system. Of this 21 per cent., however, only 1 per cent. are duly qualified by examination. The total number of apothecaries was 5,993. Only 22 of these are licensed by examination, and the vast majority practise the Chinese or Japanese system.

The law in regard to patent medicines is that hereafter any one wishing to prepare such medicine shall apply to the educational department for a license, presenting a sample of such medicine, with the names and proportions of the ingredients, directions for its use, and explanations of its supposed efficiency. A vast number of medicines are patented and sold in Japan.

Chloride of Calcium in Phthisis.—Dr. James Sawyer, of Queen's College, Birmingham, states that he gets better results in treating phthisis by combining chloride of calcium with the standard remedies, than by any other means. He is inclined to place a high value on its curative effect. He thinks it checks night-sweats, increases weight, and tends to dry up the lesions. He gives it in ten-grain doses, twice a day, after meals. There should be no mistake made by substituting chloride of "lime" for chloride of calcium.—*Brit. Med. Journal.*

The Metric System in England.—A leader in a recent issue of *The British Medical Journal* calls attention to the importance and expediency of introducing the metric system as soon as possible into medicine and pharmacy. The editor urges, that, as a beginning, the system might be introduced into those English towns where it is customary for practitioners to dispense their own medicines. The purchase of a set of metric weights and measures would be nearly all that would be necessary in order to effect the requisite change.

Sequelæ of the Fast.—During the time of Tanner's fast, and for some days after it, the papers were quite full of cases of voluntary or involuntary starvation. The literature of the subject has been greatly enriched by Dr. Tanner's performance. Nearly all the cases of starvation related in the standard works on physiology have been republished. In addition to this, a large number of new instances of prolonged abstenance from food have been contributed, upon more or less good authority. The *Lancet* publishes the case of a woman, aged sixty, who lived for forty-nine days without food, but died on the fiftieth day. She took small daily amounts of water, but had no other nourishment. There was not much emaciation. Another case was that of a man suffering from cancer of the stomach. During the last forty-one days of his life he took neither food nor drink. He suffered a great deal, and emaciated rapidly. A case is reported, on respectable authority, of a woman living in Delaware who died after a thirty-six days' abstinence from food. During this time she lost only ten pounds, weighing, when she died, 150 pounds.

A hysterical girl is reported to be living in Louisville, who has not eaten anything for forty-four days. This particular person lies in a state of "trance," and evidently belongs to the "Molly Fancher" order of light-eaters.

Those who may be classed more strictly as imitators of Dr. Tanner have been tolerably numerous. We learn of a young doctor of Lyons who essayed to go fifteen days without eating. He gave up at the end of the first week.

A starving match at $1,000 a side was proposed in this city, and a number of entries were made, but nothing came of it so far as we can learn. One of the curiosities of the mania is the Western man, who has proposed to show how long he can live upon beer alone.

A case is reported by Dr. J. C. Noyes, of Oshkosh, Wisconsin (*Boston Med. and Surg. Jour.*), of forty-five days' fasting. When seen at the end of that time by Dr. N., the patient, who had been sick for a long time, was considerably emaciated, with paralysis of the lower extremities, loss of voice, and partial dementia. The man's age was thirty-four; pulse, 56; respiration, 12; temperature, 94° F. He had taken no food for forty-five days, and no water during the last nineteen days, except to rinse the mouth. He had been unable to swallow at all during the latter period. The diagnosis could not be made with certainty.

Increase in Lunacy.—From the twenty-first annual report of the Commissioners in Lunacy for Scotland, we learn that the increase of private lunatics in England has been from 4,980 in 1859 to 7,692 in 1878. The increase of pauper lunatics has been from 31,782 in 1859 to 60,846 in 1878. This gives a total increase of from 1.87 per 1000 in 1859, to 2.76 per 1000 in 1878. There has been a similar increase in Scotland, from 1.99 per 1000 in 1859 to 2.55 per 1000 in 1879. The total number of lunatics in Great Britain is now 77,696.

Poetry for the Tenement Districts.—

In Köln, a town of monks and bones,
And pavements fanged with murderous stones,
And rags and hags and hideous wenches,
I counted two and seventy stenches,
All well defined, and several stinks!
Ye nymphs that reign o'er sewers and sinks,
The River Rhine, it is well known,
Doth wash your city of Cologne,
But tell me, nymphs! what power divine
Shall henceforth wash the River Rhine?

The International Congress of Hygiene, at Turin, will open September 6th, and close September 12th. All governments are invited to send delegates. A reduction of 30 per cent. on railroad fares is also announced.

Original Lectures.

DISEASES OF THE GREAT THORACIC ARTERIES.

A Clinical Lecture.

By Dr. E. FLETCHER INGALS.

LECTURER ON DISEASES OF THE CHEST AND PHYSICAL DIAGNOSIS, AND ON LARYNGOLOGY, IN THE POST-GRADUATE COURSE, RUSH MEDICAL COLLEGE, CHICAGO.

(Delivered May, 1880. Stenographically reported for The Record.)

Gentlemen: The first case which I present to you this morning is that of a laboring man, D. G., fifty-two years of age. He came to me recently, complaining of pain in the left side, especially near the sternum, hoarseness, and difficulty in breathing. He says that the trouble commenced last November, though he has not been well for more than two years.

Among the symptoms and signs, the first to attract our attention is a constant pain starting in the region of the second intercostal space of the left side, close to the sternum, and running downward and outward to the left of the mammary region, with occasional pains shooting into the left shoulder and arm. The patient is well nourished, and there is nothing characteristic in the expression of his countenance or in the appearance of the integuments. The pulse is soft, beating ninety-eight times in a minute, and is alike upon both sides. You will observe that the voice is feeble and hoarse. He complains of a short, paroxysmal cough, with slight expectoration of white frothy mucus, and considerable dyspnœa upon exertion. His digestive functions are well performed.

The symptoms of this case direct our attention at once to the respiratory organs. Upon examining the chest we will observe a small prominence, about two inches in diameter, with its centre in the second intercostal space of the left side, which pulsates rhythmically with the radial arteries. The chest has a peculiar marbled appearance, due to distention of the superficial veins.

Upon palpation, we find that the pulsations in the radial arteries are alike upon both sides. There is a distinct thrill felt over the tumor, and forcible epigastric pulsation is obtained. We can hardly detect the impulse of the apex of the heart against the chest-wall, but it is indistinctly felt about an inch to the left of its normal position.

By percussing in the region of the tumor, we will find an abnormal area of dulness, extending about an inch to the left of the sternum, and reaching from the first to the third intercostal space. There is no increased dulness upon the right side of the sternum or at the upper portion of this bone. Percussion over the lungs yields vesiculo-tympanitic resonance upon both sides of the chest, which, with the movements of the thoracic walls, and especially the covering of the heart by lung-tissue, would cause us at once to suspect that this man has pulmonary emphysema.

Upon auscultation directly over the prominence we obtain a loud systolic bruit, accompanied by a distinct shock, which is communicated through the stethoscope. This is followed by a diastolic bruit and shock. In listening over the apex of the heart, over an area of about an inch in diameter, a feeble systolic murmur is obtained. The same murmur is heard in the right carotid artery, but it is not heard over the aorta or any other of its branches. No murmurs whatever can be heard over the posterior portion of the chest. Auscultation over the lungs gives us the prolonged, low-pitched, expiratory murmur of pulmonary emphysema.

Upon examining the larynx with the aid of the laryngscope, we find the left vocal cord fixed in the position which it ordinarily occupies during phonation, and immovable during respiration. The right vocal cord is somewhat less mobile than in health. The cause for this immobility is paralysis of the muscles which ordinarily abduct the cord during inspiration. The paralysis is due, no doubt, to some interference with the function of the recurrent laryngeal nerve of the left side. As all of the muscles of the lower part of the larynx are supplied by the recurrent laryngeal nerve, the fact that the right vocal cord moves shows that the nerve upon that side is not greatly interfered with.

We have, in this case, symptoms and signs, some of which are present in a considerable number of diseases, so that our only method of arriving at an accurate diagnosis is by excluding those affections for which we do not find sufficient evidence. We may have in this case an aneurism of the aorta; we may have pulsating emphysema, which sometimes causes a tumor at this part of the chest; we may find consolidation and retraction of the left lung, uncovering the pulmonary artery, so as to give a peculiar pulsation at this point; or we may have stenosis of this blood-vessel, causing slight dilatation and marked pulsation; or the signs may possibly be due to a malignant tumor resting upon the descending arch of the aorta.

In the case before us, percussion and auscultation reveal the vesiculo-tympanitic resonance, increased volume, and prolonged respiratory murmur of emphysematous lungs, which at once enables us to exclude from the category of possible causes of the patient's condition, pulsating emphysema and retraction, or consolidation of the left lung, with extreme pulsation of the pulmonary artery. It is an easy matter to exclude ordinary aneurisms of the aorta, but not so easy to exclude aortic aneurisms presenting to the left of the sternum, and aneurisms, or stenosis, of the pulmonary artery. If this were an aneurism of the aorta, we would expect to find an increased area of dulness in some other position than the one here indicated, viz., the second intercostal space of the left side. This is not present. We would expect to obtain a systolic, and possibly a diastolic bruit over the arch of the aorta, propagated into the carotids, with possibly systolic and diastolic murmurs over the pulmonary area, due to pressure upon the pulmonary artery.

In this case there is a feeble systolic murmur heard at the apex of the heart, and in the right carotid, but neither in front nor behind over the aorta, nor any other of its branches; there is no shock with this murmur, and there is no diastolic bruit; the pulse is alike in the two radial arteries; there are no signs of pressure on the trachea, bronchi, or œsophagus, and therefore ordinary aneurisms of the aorta may be reasonably excluded.

An aneurism springing from the sinuses of Valsalva might give rise to the murmurs heard in this case, but could hardly cause the increased dulness on the left side, and the shock and pulsation limited to the region of the pulmonary artery. An aneurism springing from the descending arch of the aorta, or a long, pouch-like aneurism, such as was found in the case recorded by R. Douglass Powell, might give rise to increased area of dulness, pulsation and bruits in this position, but an aneurism of the descending arch large enough to cause the bulging and pulsation would usually present behind; and even if it did not, must of necessity press upon and obstruct the left bronchus, none of which conditions are present in this case. A malignant tumor, besides causing grave constitutional disturbance, would cause symptoms of pressure similar to aneurisms in this position, and would also yield a larger area of dulness; hence we exclude it. The pouch-like aneurism referred to gave signs very similar to those found in this case, excepting that there was marked throbbing of the carotids, the veins in the neck were turgid, the signs of the tumor were located about an inch lower down, and over the aorta there was a loud systolic bruit with the first sound and accentuation of the second sound with a feeble bruit. These varieties of aneurisms, then, may fairly be excluded.

But an aneurism springing from the anterior surface of the first portion of the descending arch must of necessity compress the left recurrent laryngeal nerve, as is the case with our patient; and it might so press upon the pulmonary artery as to cause stenosis of the main trunk, or one of its branches, and thus occasion a murmur like that heard in this instance, with marked pulsation; but if the pulmonary artery were not considerably dilated, or, in other words, if it had not the form which we call an aneurism, it could not occasion the increased area of dulness and bulging, or the distinct shock which attends the bruit.

Were aneurisms of this blood-vessel more frequent, we need not longer hesitate in our diagnosis; but when Dr. Stokes says, "I would not dare to make such a diagnosis!" it would be presumptuous for us to state positively that this is an aneurism of the pulmonary artery, especially as from the nature of the case this man, being a dispensary patient who is likely to pass from our observation as soon as he becomes either better or worse, we can never hope to verify the statement by the post-mortem evidence, which alone can settle such intricate cases.

Skoda states that dilatation of the pulmonary artery is not infrequent, and, as there is no distinctive line separating dilatation from aneurism, we may be justified in calling an aneurism such a degree of dilatation as will give rise to an increased area of dulness, with a shock communicated to the listening ear. Considering all the symptoms and signs in the case before us, I have no hesitancy in saying that they seem strongly to indicate the presence of this rare affection; for we have in the exact location of the pulmonary artery a strongly pulsating tumor communicating to the ear distinct bruits and shocks, both systolic and diastolic; we have pulmonary emphysema with hypertrophy of the right ventricle, which are among the most common causes of dilatation or aneurism of this artery; we have pressure on the left recurrent laryngeal nerve, which must surely occur with tumors of any considerable size in this locality, and we do not find the ordinary signs of other disease. The condition of the system favoring emphysema, with degeneration and dilatation of the pulmonary artery, would also favor atheromatous changes in the aorta, or at its valves sufficient to account for the feeble murmur heard at the apex and in the right carotid. Yet this might possibly be accounted for by an aneurism of the aorta, which, springing from the anterior surface of the initial portion of the descending arch, would compress the left recurrent laryngeal nerve, and might cause stenosis and dilatation of the pulmonary artery. Whether or not such an aneurism exists, we cannot say; but we may be reasonably certain that, from some cause, the pulmonary artery is sufficiently dilated to warrant the diagnosis of aneurism.

This is one of the rarest diseases which affect humanity. I cannot find more than six or eight cases on record, and out of nearly eight thousand cases of diseases of the chest, which I have treated during the past few years, this is the first of the kind which has come under my observation. Aneurisms will have the same effect upon the wall of this artery as upon the aorta, but from the few cases on record they seem to have generally been of the fusiform variety. They would result from causes similar to those of aortic aneurism, that is, from atheromatous degeneration and obstruction to the current of blood, which here might be due to emphysema of the lungs, or obstruction at the mitral valves; either of which interferes with the passage of blood through the pulmonary circuit, and therefore throws increased strain upon the blood-vessel.

The prognosis in such cases is grave. The exact duration it is not possible to even approximate, because of the rarity of the affection.

To judge from aneurisms of the thoracic aorta, we would be safe in saying that, under ordinary circumstances, the history could not last longer than two or four years; but possibly, by treatment, we may be able to modify the course of the disease in this case. The outcome is certain, unless treatment is very successful, and the final result will probably be due to rupture of the aneurism into some of the surrounding organs.

The treatment in such cases must be guided by what is known of the treatment of aneurisms of the thoracic aorta, and unfortunately this is generally not very satisfactory. A treatment of aneurisms of the aorta which has been found beneficial in some cases, consists of almost absolute rest, placing the patient upon the back, giving him nourishing but plain diet, consisting mainly of meat and bread, and limiting the amount of fluid which he takes daily to a few ounces. It is said that the pulsations of the heart may be reduced twenty thousand in a day by simply placing the patient upon his back; by this course some aneurisms have been greatly benefited, if not completely cured.

Such a course would be indicated in this case.

Another method of treatment, adopted in sacculated aneurisms which present near the surface, is puncture by two needles, and direction through the aneurism of a comparatively feeble electric current; the result is coagulation of the blood filling the sac, and finally, in some instances, a cure. When this method is employed the needles are passed through the base of the tumor, about two inches apart, and a current from four or five cells of a Bunsen's battery is passed for ten or twenty minutes, or until pulsation ceases. The treatment causes some pain, but ordinarily it is not severe. This treatment is only applicable to sacculated aneurisms, therefore cannot be thought of in this case.

There is still another method of treatment which has been attended with very good results, viz., the administration of iodide of potassium in large doses, which diminishes the action of the heart, and also seems to cause thickening of the walls of the artery, and contraction of the aneurismal sac. In such a case as this, where the dilatation is not very great, we would expect good results from a remedy which has the reputation of contracting the artery. The mode of administering this remedy recommended by Balfour is to give about thirty grains three times a day, with chloral or opium at bedtime to quiet the patient. The treatment must be continued for several weeks or months.

In case the symptoms of iodism appear, it should be suspended for a day or two. In a case which I presented to the class three years ago, we had an aneurism of the abdominal aorta, which appeared to be about three inches in diameter; the patient complained of pain, which had lasted three or four months, and which prevented him from attending to his vocation.

In that instance, I gave the iodide of potassium faithfully, with the result of removing the pain completely in two or three months. and ultimately of diminishing the size of the tumor about one-half. The man felt perfectly well afterward, and discontinued the remedy after a year and a half. He is now about his ordinary work, feeling as well as ever.

The remedy in that case was not given in such large doses as recommended by Balfour. With this case I began with ten-grain doses of the iodide of potassium, giving it three times a day; he has since taken it for a few days four times a day, and yesterday I ordered twenty-grain doses four times a day. The flushed nose and suffused eye show that the remedy is acting vigorously, but the patient does not complain of the symptoms of iodism; already the pain in the chest is diminishing, and therefore we will continue the same course of treatment. If unpleasant symptoms arise, the remedy will be discontinued for a short time. He should take the iodide with three or four ounces of water, and at other times drink as little as possible. The first evidence of benefit from iodide of potassium will be diminution or removal of the pain.

Case II.—I have another case to show you this morning, which is also unique. This lad's name in Bennett; he is fourteen years of age, and has for some time been an errand boy, in one of our large retail stores. He has no trouble whatever with his respiration, no cough, and his countenance is ordinarily clear. The only evidence of imperfect circulation is the congested condition of the ear. The patient was brought to me by one of the gentlemen of the class, on account of a loud murmur which can be heard over the chest, and which has probably existed from infancy, as the doctors long ago told him that there was something wrong with the heart. There is no apparent trouble, except this very slight congestion. In feeling over the upper portion of the sternum I obtain a distinct thrill; upon auscultation I obtain a very loud systolic murmur, which is heard all over the chest in front, but with greatest intensity close to the edge of the sternum in the second intercostal space of the right side; it is also heard behind with great intensity over the region of the aorta and under the left scapula; it is heard under the right scapula, but not so intensely. This murmur is heard best in the aortic area, close to the border of the sternum.

Upon examining the pulsation of the radial arteries, I find it alike on both sides; I notice nothing peculiar about the chest; and very little, if any, enlargement of the heart.

Now, if we obtained such signs as this with no history, we would suppose that there was obstruction at the aortic valves; but this murmur has undoubtedly been present for several years. But had obstruction at the aortic orifice really existed for this length of time, the heart, before this, must have become considerably hypertrophied, and he would not be able, as he is now, to perform the ordinary duties of a boy of his age. The symptoms and signs ordinarily attending obstruction at the aortic orifice are not present in this case, and the lad is not old enough to suffer from atheroma; he is not anæmic, and therefore we must suspect an affection of which I spoke to you in a former lecture, viz., stenosis of the aorta. You will recollect that I told you this condition is usually found between the point of origin of the left subclavian artery and the junction of the ductus arteriosus with the aorta.

It seems usually to be produced just after birth, by a clot forming in the duct and extending into the aorta; the contraction of this clot is attended by more or less inflammation of the artery, which, by the contraction of the plastic lymph becomes corrugated or wrinkled; or a band of cicatricial tissue sufficient to throw the blood into an eddy, and thus cause a murmur, may stretch across one side of the artery; or there may be a ring-like construction, or the aorta may be perfectly occluded.

The signs of this affection are a loud murmur, especially in the aortic area, but generally heard over the whole chest, and when the contraction is very great, dilatation of the superficial arteries, especially of the intercostal, and feebleness or absence of the pulse in the popliteal and tibial arteries, associated, if the occlusion is complete, with imperfect development of the inferior extremities and generative organs.

In this case I find that there is no apparent dilatation of the superficial arteries; still we have a loud murmur, feeble pulsation in the arteries of the inferior extremities, and a history of the affection having existed from early childhood. We therefore conclude that in the case before us there is partial stenosis of the aorta, though probably of moderate degree.

The prognosis in this affection is usually unfavorable, though individuals sometimes live for many years after the first signs are noticed.

In this lad we have no symptoms or signs that indicate great interference with the function of the heart, and we may therefore give a favorable prognosis. As to treatment, we simply recommend him to be careful about his work or play, not to throw unnecessary strain upon the heart, or cause it any labor which can be avoided.

◆

The Princeton Epidemic and its Critics.—A silly item has appeared in reference to the epidemic of typhoid fever which took place last spring at Princeton, N. J. Dr. McCosh is attacked with much turbulent rhetoric, because he referred to the matter as a dispensation of Providence, and, presumably, did not have the drainage attended to. The venerable president is also accused of being a disbeliever in evolution. The facts of the matter, as given in *The Sanitary Engineer*, show that the college authorities had done their best to make the sanitary arrangements of the buildings perfect. The accident to the plumbing, which possibly caused some of the cases of fever, was one that could not have been foreseen, and was what is always liable to happen in any place except Hygeiopolis. The expression "providential dispensation" was an innocent one; and surely a man may still deny that he sprang from ascidians without being subjected to foolish ridicule.

Original Communications.

THE TREATMENT OF POST-PARTUM HEMORRHAGE—WITH CASES.

W. E. FOREST, M.D.,

NEW YORK.

CASE I.—Mrs. D., age 25, fifth child, labor normal and moderately rapid. The only thing noticeable about the case was the presence of a very large subperitoneal fibroid on the fundus of the uterus, that could be felt through the walls of the abdomen. During the second stage of the labor the patient inhaled a small amount of chloroform. Ten minutes after the birth of the child the placenta was expelled by contractions excited by ergot and by Credé's method. While my hand was still kneading the uterus, I felt it relax and enlarge, and I discovered a stream of blood flowing from the vagina. I immediately carried my hand into the uterus and turned out the clots, and then discovered two large *submucous* fibroids at the fundus. The fact that the woman was a quadroon explained the presence of these three good-sized fibroids; while the presence of the fibroids explained perhaps the post-partum hemorrhage. The uterus, after a short contraction, again filled with blood. Meantime the nurse was trying to get the Davidson's syringe in working order that I might use hot-water injections. In this attempt she failed completely, and I despatched the husband after a new syringe. During this delay, despite my manipulations of the uterus, with one hand on the abdomen and the other in the vagina and uterus, the hemorrhage continued, and my patient began to present signs of collapse. In this alarming emergency I made my first trial of *vinegar*. Dipping a cloth into a cup of vinegar, I rolled the cloth into a wad and carried it into the uterus. The effect was magical, and my hand and the cloth were quickly expelled by a strong contraction. About two minutes later the uterus commenced to relax, and a slight flow commenced, which was speedily checked by carrying the cloth into the cervix.

The patient made a good recovery.

CASE II.—Mrs. M., age 38, mother of seven children. Called at midnight in consultation with another physician. Found both arms hanging from the vagina with the shoulders impacted in the pelvis. The presence of the second arm was due to the attending physician mistaking the hand for the foot when he attempted version, and thus he had brought down the second arm. Ether was administered and podalic version was attempted. Owing to the long-continued impaction of the shoulder, this was exceedingly difficult, and it was fully an hour before the child was delivered—dead.

While I was making attempts to resuscitate the child the attending physician called my attention to the condition of the mother. She had not recovered from the anæsthetic, and now she was collapsed and pulseless. I found the uterus distended with blood and a profuse flow from the vagina. The collapse I supposed to be due to the exhaustion, the long-continued use of the ether, and the hemorrhage combined. I introduced my hand and turned out the clots, but the uterus again refilled. In this alarming emergency, when every moment's delay was dangerous, and when there was at hand not even a Davidson's syringe, I resorted again to the use of vinegar. I quickly carried a cloth saturated with strong cider-vinegar into the uterus, with the result of causing immediate contraction and the checking of the hemorrhage. A second application caused firm contraction of the uterus.

The woman made a good recovery.

CASE III.—Mrs. A., age 25, fourth child, labor tedious. Soon after placenta was delivered, and while my attention was turned to the child, the mother became very faint. I found the uterus very much enlarged and blood flowing from the vulva. The woman was blanched and restless and had all the signs of an alarming hemorrhage. I promptly introduced my hand into the uterus and turned out the clots, and then as soon as possible carried the nozzle of a Davidson's syringe into the uterus and injected hot water. Firm contraction of the uterus came on speedily, and the bleeding soon ceased. During the application of the hot water a faint color came into the woman's lips, as if the hot injection had acted as a stimulant to the general circulation. The woman made a good recovery.

CASE IV.—Mrs. H., age 26, primipara. At the beginning of the eighth month of pregnancy she was suddenly taken with a convulsion. I saw her in consultation a short time after the first convulsion. An examination of her urine showed it to be loaded with albumen. She had œdema of the feet very marked, puffiness of the hands and face, and had had œdema of the lungs, though this condition had now disappeared. The patient had a staring look, irregular pupils, and was much confused mentally. In spite of treatment the convulsions followed each other in rapid succession until chloroform could be procured and the patient kept under its influence. In this condition we determined to induce labor immediately. While the patient was kept under the moderate influence of chloroform, the Barnes dilators were used, and in an hour the os was dilated so as to admit the application of the forceps. Thus far the os had dilated easily, slight pains had come on, and everything promised a speedy delivery. The lips of the os were, however, thick and leathery, and instead of retracting over, the forceps came down before them and were soon presenting at the vulva. No amount of traction or manipulations with the hand could bring the head through the os uteri until I had nicked the os with a bistoury in several places and had allowed free bleeding from the incisions. Then the head was delivered with only a moderate laceration through the posterior lip of the os. Meantime my patient having come partly out from the influence of chloroform, went into another severe convulsion. This was the sixth convulsion, and she was never conscious again. The child was dead. The placenta was speedily delivered by making pressure upon the fundus uteri. Immediately after the placenta was delivered flooding commenced. Fearing that this accident might occur, owing to the complete uterine inertia that had been present during the latter part of the operation, I had standing by the bed a Davidson's syringe and a kettle of hot water. The gentlemen assisting me gave the patient two drachms of ergot hypodermically while I at once turned out the clots from the uterus, and carrying the nozzle of the syringe into the uterus, commenced the injection of hot water. The uterus made a feeble effort to contract and expelled my hand, which was still within the uterus, but it almost immediately relaxed and the flow recommenced in an alarming manner. I again carried my hand and the nozzle of the syringe into the uterus and injected a large quantity of water as hot as I could bear my hand in. There was no further contraction of the uterus and the flooding was more profuse than ever. The condition of my patient was now very alarming. She had been under the influence of chloroform about four hours, except for a few moments' interval, during which she promptly went into convulsions; she was losing blood very rapidly, and the methods for controlling the hemorrhage that had never failed me before were now utterly useless. My hand in the uterus seemed to be in a loose, flabby pocket. In this emergency I despatched a messenger to the nearest drug store for tincture of iodine, and during his absence I carried the largest-sized Barnes dilators into the uterus and pumped it full of ice-water. Pressure was at the same time made upon the abdominal aorta and cold water dashed upon the patient's abdomen. No contraction of the uterus and no check to the hemorrhage. At this juncture the iodine arrived, and diluting one-half with hot water I immediately injected it into the uterus. The effect was magical; the uterus contracted quickly and the bleeding ceased. After a few minutes a slight relaxation of the uterus took place, but a second injection of iodine caused a firm and continuous contraction. In spite of every effort to stimulate my patient's flagging energies she steadily sank, and died in a few minutes. The uterus remained firmly contracted after death.

Case V.—Mrs. M., age 26, taken in labor June 15, 1880. I was called to see her at 1 P.M.; found the os undilated, vertex presenting, pains slight and recurring about every half-hour. I learned that at her previous labor a year ago she had a very difficult delivery, that the child was delivered by forceps, dead-born, and I found on examination that the perineum was lacerated completely through into the anus, and that she had prolapse of the bladder.

The labor progressed very slowly, and at midnight the os was dilated to the size of a copper cent. The woman was tired and sleepy, but not exhausted, and under the influence of morphine rested well until morning. At 10.30 A.M. I gave chloroform, and dilated the os with my fingers until I could apply the forceps, when I succeeded in delivering the child safely in about ten minutes. The child was a male, of good size, and alive. After the delivery of the child, the mother rallied well from the chloroform, and everything seemed favorable. The uterus contracted on the placenta under manipulations on the abdomen, but the placenta could not be delivered.

After nearly an hour's manipulations the placenta was still undelivered, and now a stream of blood was flowing from the vagina. I then passed my hand within the uterus, and found the placenta adherent to its anterior wall. The upper border of the placenta was detached, and from this site I judged that the hemorrhage proceeded. The rest of the placenta was firmly adherent, and on attempting to detach it, I found that its maternal surface had undergone calcareous degeneration. With considerable difficulty I succeeded in detaching the placenta with my fingers, tearing it several times in so doing. On removing the placenta, a profuse hemorrhage followed. I at once turned out the clots, and carried a sponge dipped in vinegar into the uterus, and made compression over the fundus and upon the abdominal aorta. The flow still continued, and I repeated the application of vinegar several times. The flow was not checked, and I commenced injecting hot water into the uterus. My hand upon the woman's abdomen could feel the uterus distend with the water, much as would a rubber bag, but no contraction of the uterus followed.

My patient was now in a most dangerous state. In spite of the fact that her head had been lowered, and that she had swallowed glass after glass of undiluted brandy, she was blanched and unable to see her friends standing around her. Owing to a misunderstanding, the iodine, for which I had sent some time before, did not arrive, and as the most liberal injections of hot water and the use of vinegar, with simultaneous compression of the fundus and abdominal aorta, and the exhibition of ergot, had failed to control the flow, I despaired of the woman's life. At this moment the messenger arrived with the tincture of iodine. I at once diluted two ounces of the iodine with an equal amount of water, and injected it within the uterus. The uterus contracted almost immediately and expelled its contents. It then relaxed after a few minutes, and a slight flow recommenced, when I injected *two ounces of undiluted tincture of iodine.* There was no more bleeding, and the uterus remained contracted.

On account of the feeble condition of my patient, I bandaged her extremities with roller bandages and had her kept quiet, with her head low. She made a good recovery, and had no septic symptoms during her convalescence.

Case VI.—Dr. Alexander Hunter related to me the following case: In July, 1876, I was sent for in great haste by a midwife to see a woman who was bleeding to death. On my way to the case I procured a bottle of tincture of iodine, perhaps half an ounce. I found the woman in a room at the top of a tenement-house, the child born, but the placenta undelivered, and a very serious flooding taking place. The case was a desperate one, and there was not even a Davidson's syringe in the house. I at once removed the cork from the bottle, and then carried the bottle of iodine up to the fundus uteri with my hand, and allowed the tincture of iodine to run out. I then allowed my hand to remain in the uterus until a contraction came on, which was almost immediately, when my hand, the placenta, and the other contents of the uterus were expelled. There was no further hemorrhage, and the woman made a good recovery.

These six cases of post-partum hemorrhage (to which I might have added the notes of two or three others of minor importance) were typical cases of this most dangerous accident. In the treatment of them I employed nearly all the known methods, namely, ergot internally and hypodermically; the introduction of the hand into the uterus and removal of the clots, combined with compression of the uterus through the abdominal walls; compression of the abdominal aorta; the application of vinegar to the inner surface of the uterus; the introduction of ice and of the Barnes dilator, filled with ice-water, into the uterus; the injection of hot water; and, finally, the intra-uterine injection of tincture of iodine.

In studying the histories of the cases given above it will be seen at a glance that these methods of treatment have different values in the different kinds of cases, and that methods of treatment that are useful in mild cases may be more than useless in severe ones. Let us review them briefly.

The introduction of the hand into the uterus and the removal of the clots is a proceeding of the utmost importance in every case. In some cases this introduction of the hand, combined with pressure upon the fundus of the uterus with the other hand, is sufficient to excite the uterus to contract and thus to control the hemorrhage. In any case, before an application can be properly made to the interior of the uterus, the hand must be introduced and the clots removed.

The use of the Barnes dilator should be placed in the same category as the ether-spray and the Faradic battery, as methods more fanciful than practical. They are undoubtedly of value in some cases, if the physician should happen to have such instruments with him when post-partum hemorrhage occurs. But in severe cases they would not control the hemorrhage. In cases where there is a slight but continuous flow after delivery in a debilitated person, the battery would be of use in exciting the uterus to contract firmly.

The administration of ergot hypodermically is a valuable measure in post-partum hemorrhage, and it may be used in conjunction with any of the other methods of treatment. But ergot should be given per orem only as a prophylactic measure. The patient's stomach should be used, during the hemorrhage, for the absorption of brandy and other stimulants.

The compression of the abdominal aorta may be used to good advantage, especially in thin women. If an assistant be present he can manipulate the uterus and compress the abdominal aorta at the same time.

The use of ice and ice-water within the uterus is a measure recommended in all text-books. It is a valuable measure in some cases, but if it does not speedily control the hemorrhage its use must be discontinued. The effect of cold is first to excite uterine action, but if it be long continued, it paralyzes the muscular fibre, so that the hemorrhage becomes more profuse than before. *Hot water*, on the other hand, when injected into the uterus, is one of the most efficient methods we have for controlling post-partum hemorrhage. Not only will it usually check the hemorrhage, but it seems to stimulate the general circulation as well. I have observed the pallid lips of the patient become red while administering intra-uterine injections of hot water for post-partum hemorrhage. The water must be given as hot as it can be borne, injected rapidly and in large quantities. I once believed that intra-uterine injections of hot water were an efficient method of treatment for every case of post-partum hemorrhage, but in Cases IV. and V. it failed entirely.

The intra-uterine injection and application of vinegar is one of those methods of treatment that was well known to the older writers on obstetrics, but in the advance of medical knowledge it seems to have been left behind and forgotten. It is but recently that I have seen this method advanced as a new and original plan of treatment. The vinegar controls the hemorrhage, not through its styptic qualities, but by stimulating the uterus to contract. In many cases it is an efficient method of treatment, and the strongest vinegar may be freely applied to the interior of the uterus without fear of causing bad results.

One advantage this method possesses over many others is that the necessary materials are at hand in every house—a piece of cloth or sponge, and a little table-vinegar, are the means for controlling some of the most alarming hemorrhages.

Tincture of iodine as an intra-uterine injection to control hemorrhage was brought prominently to the notice of the profession by Dr. T. A. Emmet, of this city. So long ago, however, as 1857, Dr. Dupierris, of Havana, Cuba, published an article, giving the histories of three cases of post-partum hemorrhage where injections of tincture of iodine were made into the cavity of the uterus with the most excellent results. But his cases failed to attract the attention they deserved, and his method did not then come into practice.

Speaking from my own experience, I should say that the injection of tincture of iodine is the most safe and by far the most efficient method we possess for controlling post-partum hemorrhage. A study of Cases IV. and V. will show that almost every other method had been tried and had failed before iodine was resorted to, and yet this controlled the hemorrhage speedily and completely. It is in just such cases as this that the striking superiority of iodine over *everything else* will be manifested.

In this country the virtues of iodine in post-partum hemorrhage are quite well understood, but in England, and, so far as I know, in other European countries, it has not been used. English obstetricians, for the last few years, have followed the teachings of Dr. Barnes in severe cases of post-partum hemorrhage; namely, the injection into the uterus of the solution of persulphate or perchloride of iron. The results of such treatment—as given to us in the reports of a discussion before the London Obstetrical Society, in 1873, and in reports of cases in almost every number of the *Obstetrical Journal* of Great Britain and Ireland since that time—are not such as to lead the profession in this country to adopt such treatment in preference to the use of tincture of iodine. In the report of autopsies after the use of the persalts of iron as a uterine injection, the uterus was found, in some cases, to be filled with hard clots of decomposing blood, while pus and hard thrombi were found in the uterine sinuses. In some cases the internal surface of the uterus had sloughed away in a mass after the use of the iron. Dr. Snow Beck, in the discussion mentioned above, stated that he had seen nine or ten cases result in death after the use of the salts of iron. He believed that the styptic enters the uterine sinuses and coagulates the blood in them, and that when decomposition takes place, as it certainly must, everything is favorable for the absorption of matter and the development of septicæmia.

While then the injection of a solution of the persalts of iron will usually control post-partum hemorrhage, its use is not unattended with danger.

In summing up the advantages of the iodine treatment of post-partum hemorrhage we may state them briefly as follows:

1st. Iodine controls the hemorrhage, not by coagulating the blood within the uterus, but by exciting the uterus to contract. The blood is expelled in a liquid form, and hence, instead of leaving the uterus filled with a mass of hard, sticky clots, ready to undergo decomposition, the uterus is empty and disinfected.

2d. Tincture of iodine has never, so far as I can learn, caused any bad result, even when injected into the uterus in full strength. Thus, in Case V. nearly six ounces of tincture of iodine were injected (four of them without dilution), and yet no bad effects followed its use.

3d. The iodine treatment never fails to control the hemorrhage.

There have been other methods than those given above brought forward for the treatment of post-partum hemorrhage, but none of them, I believe, will be found superior to those given. In the treatment of disease it is a good plan to try the best remedy first; and while this is true in most cases, it is especially true in that alarming and dangerous accident, post-partum hemorrhage.

No. 1 Charlton Street.

A CASE OF COMPLETE TRANSPOSITION OF THE VISCERA OF THE THORAX AND ABDOMEN.

Reported by Dr. WILLIAM PIERSON, Jr.,
ORANGE, N. J.

Mr. G——, aged sixty-five; born in New York; married; six feet in height; robust; lumber merchant. Died July 31, 1880. Early in childhood he observed that the impulse of his heart could be felt on the right side of the chest. It gave him no concern, as he supposed it was the proper place for it.

As he grew older, and learned that the heart was ordinarily on the left side, he consulted physicians in reference to it.

Some supposed it was a congenital transposition, others, that the heart had been pushed over by pleuritic effusion.

Until about a year ago he had enjoyed continuous good health. He was then attacked with dyspnœa, which became more and more serious until the time of his death. He also had anasarca, and his urine contained albumen and casts.

The impulse of his heart was just below the right nipple and about three inches from the centre of the sternum. The valvular sounds were normal. There was an audible bruit over the upper part of the sternum. The interest in the case centres in what was revealed at the autopsy, viz., a complete transposition of the viscera of the thorax and abdomen.

On laying open the abdomen the liver was found on the left side, the lobe to the left being the largest. The proportions of the liver were normal, and the relations to each other of the lobes and fissures were as usual, only they were in inverse order from right to left. The round ligament was to the left of the median line. The gall-bladder bore its usual relation to the liver; but an attack of hepatic colic would have been on the left side. The cardiac end of the stomach was to the right, the pylorus and duodenum to the left. The spleen was found in the right hypochondriac region. The cæcum was in the left iliac fossa, the sigmoid flexure of the colon in the right, and the rectum entered the pelvis from the right.

When the sternum was raised the viscera of the thorax was also found transposed. The apex of the heart pointed to the right side, the left (ordinarily the right) ventricle being anterior. The aorta was given off to the left of the median line, the arch being directed to the right and descending on the right side of the vertebræ. The innominate artery was on the left, and as usual, the first branch; then, in order from left to right were given off the right common carotid and right subclavian arteries.

The venous side of the heart was toward the left, the venæ cavæ being on the left side and entering the left auricle (normally the right).

The right lung had two lobes, the left lung had three.

The pathological conditions were as follows:

The kidneys contained numerous cysts, and were smaller than normal, the cortex being very much contracted. They presented the appearance of the granular kidney.

In the pleural cavities there was a large amount of serum; most of this had probably settled here by gravity since death, as there had been marked anasarca during the last few days. The pericardium contained a quart of blood, with soft dark clots.

The visceral pericardium around the left pulmonary artery was deeply ecchymosed; this condition extended up the origin of the aorta for one inch and a half. No break could be found in the pericardium to account for the presence of the blood. On section, this ecchymosed condition was seen to correspond to a clot effused between the serous and fibrous layers of the pericardium, the posterior coronary artery passing directly through it. Both coronary arteries were carefully examined, but neither of them presented a source for the hemorrhage, although the posterior was very much enlarged and the seat of atheromatous deposit. The other vessels at the base of the heart were all carefully examined, but none of them presented any rupture by which blood could have escaped.

The aorta was atheromatous and dilated, and its tissue tore like wet paper.

The heart was hypertrophied, particularly the right (the arterial, normally the left) ventricle, with dilatation of its cavity; but the valves were healthy and competent.

The patient presented the pathological conditions usual to Bright's disease.

The clot at the base of the heart was probably due to rupture of small diseased arteries running in the layers of the pericardium, and was probably the source of the blood found in the pericardium. The symptoms noticed in life may easily be accounted for by the disease of the kidneys and the consequent condition of the arterial system. His death, which was sudden, was probably due to syncope.

The following gentlemen were present and assisted at the autopsy:

Drs. J. C. Young and Van Wagener, of Newark; Dr. Wilmarth, of East Orange; and Drs. Bayles and Harvey, of Orange.

Reports of Hospitals.

PENNSYLVANIA HOSPITAL, PHILADELPHIA.

Clinical Service of Dr. R. J. LEVIS,
SURGEON TO THE HOSPITAL.

FRACTURE OF THE PATELLA TREATED BY A MODIFICATION OF MALGAIGNE'S HOOKS.

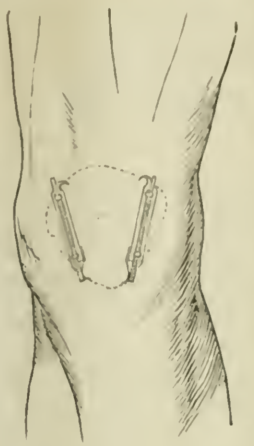
In this hospital fractures of the patella are exceedingly common, but it has been only within a few years that the treatment has been at all satisfactory. Previous to that time the attempt to bring the fragments into apposition was usually more or less unsuccessful, and the various dressings with splints and strips of adhesive plaster were uncomfortable and inefficient. Now, I always use the modified Malgaigne's hooks, and am well pleased with the results obtained by their employment.

First, however, let me speak of the causation and diagnosis of patella fractures. It was formerly believed, and is still maintained perhaps by some authorities, that this bone is usually broken by direct violence. Such is not the case in the majority of instances. Comminuted fractures undoubtedly do occur at times from direct violence to the part, but the well-known simple transverse fracture of the patella results from muscular contraction. This is evident from the fact that usually the patient falls after the fracture has occurred, and shows no abrasion or contusion of the integument of the knee. He tells you that he slipped, endeavored to regain his balance, then felt pain in his knee, and perhaps fell backward. The same thing is shown by the fact that sometimes the muscular contraction tears the extensor muscle from the bone, instead of fracturing the patella itself. Such a case was shown by me to the class a year or two ago. These instances are rare, because the bony tissue will rupture more readily than the fibrous tissue forming the tendon of the quadriceps muscle. There have been only two cases of rupture of the tendon admitted into this hospital during many years, but fractures of the bone are exceedingly common. In one case it was suggested to cut down upon the torn tendon and suture the parts together, but the proximity of the synovial membrane made the operation one of some risk, and it was not adopted. Moreover, there seemed to be a slight attachment of the vastus externus untorn, though the main part of the quadriceps was separated from the bone to a sufficient extent to exhibit a deep gap. The limb was kept extended, and the patient recovered fair use of his limb, though there still remained a slight depression just above the patella, showing the seat of injury. The other patient referred to did not gain such good use of his leg, and when discharged was obliged to walk with a cane.

The cause of simple transverse fracture, then, is the violent contraction of the quadriceps extensor muscle.

The symptoms of the injury are: inability to extend the leg, a distinct gap between the fragments, crepitus on manipulation when the pieces of bone have been brought together, and some effusion in the joint. The upper fragment may be drawn up several inches, but the lower retains its normal position, because the ligament of the patella has no muscular power to cause displacement. Flexion of the limb greatly increases the separation. It must be remembered that occasionally fracture occurs without causing much tearing of the fascia overlying the bone, and then the displacement will be slight and the diagnosis somewhat difficult. The cure in such cases is good with any form of treatment. In other instances, as in a case in the ward some years ago, the force may be great enough to tear open the joint and produce a compound injury. The patient, a woman of middle age, had sustained a fracture of ordinary kind some months previously. The knee was still somewhat stiff, and ligamentous union with about one-half inch separation existed. She slipped and fell, and when brought to the hospital exhibited a refracture of the bond of union with a transverse rupture of the tissues directly into the joint, so that the articular surfaces of the femur and tibia were exposed. Notwithstanding the serious complication, she speedily recovered, though there remained much separation of the fragments due to the impossibility of applying apparatus. The diagnosis of fracture of the patella is generally an easy matter, though at times the condition may be obscured by the amount of swelling due to the accompanying synovitis. Indeed, it is probable that the effusion has some agency in increasing the amount of separation of the fragments.

The treatment by attempting to draw down the upper fragment with strips of adhesive plaster, or a combination of straps and splints, I have abandoned. These measures tend to interfere with the blood-supply of the bone, and are uncomfortable to the patient. Moreover, it is rarely that perfect apposition can be obtained. My former method was to elevate the limb with the knee extended, to relax the rectus muscle, and then to apply strips of plaster above the upper fragment to draw it downward, and below the lower one to steady it. At the present time I employ a more radical and more efficient method. Many years ago Malgaigne devised the hooks which bear his name for the treatment of this fracture, but they were used for a few years and then discarded by the profession. Recently, however, this means of getting approximation has been revived in this hospital, and Dr. Morton and myself seldom, if ever, employ any other form of treatment. I have separated the double hooks of Malgaigne, and use single hooks, which, as you see, necessitates the employment of two screws. The fragments can be more accurately adjusted by the two sets of single hooks than by the double hooks originally used. The bone's surface is uneven, and as the line of fracture is frequently slightly oblique and irregular, it was found difficult to get the double hooks firmly embedded. With the modified hooks which I employ, trouble of this kind does not occur. I am inclined to have the next set of hooks made with clamps, somewhat like the obstetric forceps, instead of with screws; for after the parts are properly adjusted the long screw is in the way, and it is seldom required to tighten the screw after the first application of the dressing. The method of treating fractures of the patella, then, is as follows: when the patient is admitted the limb is placed upon a pillow and kept at rest for a week or ten days, with some anodyne or evaporating lotion applied. If there is very great synovial effusion, aspiration may be resorted to in order to hasten its removal. When inflammatory symptoms have subsided, the patient is anæsthetized, and the parts held together by the fingers of an assistant. I then, as you see, thrust the hooks firmly into the tissues overlying the bone, and screw the corresponding hooks firmly together until I find the fragments are in close and accurate apposition. It is not absolutely necessary to give an anæsthetic, but we ordinarily do so. In inserting the hooks it is not possible to wound the cavity of the joint, as I have verified by experiments on the cadaver. The knee is then kept extended, and carbolized oil is applied over the points of puncture, which do not give pain or incline to suppurate. There forms about the hooks a little crust of lymph which I leave undisturbed. It is not likely that all the force I apply caused the instrument to penetrate into the bone itself, but the points remain embedded in the tendon and fascia. The patient will complain less of this form of treatment than of the method in which the limb is enveloped in adhesive plaster and bandages. To those who have not followed out this treatment it may seem to be accompanied with risk of erysipelas and abscess, but such has not been my experience. I use this plan of treatment exclusively in hospital and private practice. At the end of four or five weeks the hooks are removed, and the patient



allowed to go about with a silicate of sodium dressing, to keep the knee rigid. Subsequently this is removed and passive motion instituted.

The number of cases in which the various forms of hooks have been used in the hospital is quite large; and my experience of the cases in my own and in Dr. Morton's ward, coupled with a number in my private practice, has caused me to change my former opinion, which was averse to the employment of Malgaigne's hooks.

The apposition obtained is usually almost perfect, and it may be asserted that it is the only method by which osseous union can reasonably be expected. In some of my cases measurement has shown the two patella to be of the same length after the hooks have been removed; and in a recent case it was not possible to be certain of the exact line where fracture had existed. This is far better than the separation of a half or three-quarters of an inch, so often seen after treatment by the usual methods.

The hospital has upon its records many cases treated by hooks, which will, I think, convince you that the treatment here described is preferable to any other. This conclusion, you must recollect, has not been reached hastily; for it is three or four years since I treated the first case by hooks, and many others have been cured by the same measures. In all the cases which I have treated in this manner the result appears to have been complete synostosis or bony union, and there have occurred no severe local or constitutional symptoms.

Progress of Medical Science.

Copper a Preservative against Cholera and Typhoid Fever.—At the meeting of the *Académie de Médecine de Paris*, on March 30th, M. Burq read an interesting paper on this subject. The paper gave the particulars and results of a number of observations and researches, which prove that workers in copper enjoy an almost complete immunity from cholera, and also to an almost similar extent from typhoid fever. It seems to be necessary for this immunity, however, that the copper-powder with which the system is impregnated should possess a certain degree of purity, *ex. gr.*, not be attenuated too much by admixture with iron-dust, and that the exposure to the copper-dust should be constant. In view of these facts, the therapeutic value of the internal administration of copper in typhoid fever and cholera becomes a question of much interest.—*Jour. de méd., etc., de Bruxelles*, May, 1880.

Coca in the Opium-Habit.—In the *Louisville Medical News* for May 29th, Prof. Palmer published an article on coca as an antidote to opium-eating, and gave abstracts of a few cases in which he had tried it with the happiest results. The article evidently attracted general attention, and several additional cases of the successful use of coca to break up the opium-habit have already been reported from various sources. The coca seems to act as a general nerve-stimulant, counteracting the terrible depression which follows the attempt to break off the use of opium, and curing the craving for that drug. In most of the cases so far reported, a cure was effected in a little over a week. In some of them the opium was discontinued gradually, but Dr. Palmer advises that the break-off should be made at once. According to him, the coca is to be used as *a substitute* for the opium. It should therefore be taken as freely as the cravings of the system for opium may demand—tablespoonful doses of the fluid extract several times a day, more or less, as needed.

Piscidia Erythrina (Jamaica Dogwood)—A New Narcotic.—This tree belongs to the family leguminosæ, and grows in Jamaica in arid districts. The active principle is contained mainly in the bark of the roots. The drug is stated to be a direct sedative, producing narcotic effects which are refreshing, and not followed, like opium, by hyperæmia of the brain, nausea, and general nervous disturbance. Dr. Isaac Ott has recently studied experimentally its physiological action, and published the results in the *Detroit Lancet* for June. As the active principle has not yet been extracted, he used in his experiments a so-called infusion, obtained by mixing an ounce of the fluid extract of the bark with an equal quantity of warm water and evaporating the whole down to about five drachms, the object being to get rid of the alcohol. His experiments show that we have in piscidia a drug capable of producing death by arrest of the respiratory apparatus. Frogs seldom recover from a moderate dose of the drug. The following conclusions are drawn from the experiments:

1. Piscidia is narcotic to frogs, rabbits, and men.
2. It does not affect the irritability of the motor nerves.
3. It does not attack the peripheral ends of the sensory nerves.
4. It reduces reflex action by a stimulant action on the centres of Setschenow.
5. It produces a tetanoid state by a stimulant action on the spinal cord, and not by a paralysis of Setschenow's centres.
6. It dilates the pupil, but the dilatation passes into a state of contraction upon the supervention of asphyxia.
7. It is a salivator.
8. It increases the secretion of the skin.
9. It reduces the frequency of the pulse.
10. It increases arterial tension by stimulation of the monarchical vaso-motor centre.
11. This increase of tension is soon succeeded by a fall, due to weakening of the heart itself.

If the action of piscidia be compared with that of chloral, it is found that it has no such dangerous action on the heart as the latter, nor such an energetic action on the respiratory apparatus. Unlike atropia, it does not paralyze the motor nerves nor the chordæ tympani, does not arrest the sudoral secretion, does not paralyze the pneumogastric, and does not elevate greatly the arterial tension; like atropia, it dilates the pupil. Like morphia, it produces sleep, heightened excitability, spinal convulsions, general paralysis, and stimulation of the main vaso-motor centres; unlike it, it dilates the pupil. It may be mentioned here that several cases have been reported lately in which piscidia was used successfully as a substitute for opium in the treatment of various neuralgias.

The Odor of Iodoform.—According to Dr. Lindemann, the balsam of Peru completely masks the odor of iodoform, three parts of the balsam neutralizing perfectly one part of iodoform. To them may be added as vehicle, eight parts of vaseline, glycerine, alcohol, or collodion. The balsam and iodoform should be carefully mixed together first, and the other ingredients added afterward.

Simple Method of Reducing Paraphimosis.—In some severe cases of paraphimosis, where the ordinary manipulations failed to effect a reduction, M. Bardinet employed the following manœuvre with success: he inserted the convex ends of three hair-pins at regular distances apart, beneath the constricting ring, and over the bridge thus formed the foreskin was drawn down with the greatest facility. —*Allg. med. Cent. Zeit.*, June 2, 1880.

Occlusion of the Coronary Arteries.—The arrest of the blood-supply to the walls of the heart in consequence of disease in the coronary arteries, is a well known pathological factor in certain morbid states of the heart's walls. The effects of such arrest have been studied experimentally by several investigators, who found that it caused rapid enfeeblement of the heart's action. Lately, the subject has been reinvestigated by Grünhagen and Samuelson, who have ascertained several new facts. By keeping rabbits under the influence of curare and artificial respiration, they were able to compress the coronary arteries by means of forceps, and to do this repeatedly, so as to observe the comparative effects of arrest and renewal of the flow of blood. The compression caused at once a retardation of the rhythmical action of the heart, especially of the left ventricle, while the contractions of the right ventricle were at first more rapid, and then were also slowly retarded. The slowing of the action increased the longer the compression lasted, or after several repetitions, until finally the contractions ceased, first of the left and later of the right ventricle. A second effect of the compression was weakening of the heart's contractions. This was also observed and estimated by the manometer by Bezold, and it was corroborated by Samuelson with a galvanoscopic frog. As soon as the heart became pale and the contractions were less frequent, these were no longer sufficiently powerful to excite the sciatic nerve of the frog, but after the current of blood was renewed, the nerve again responded. The experiment was repeated several times in the same animal. A third fact noted was that the compression of the left coronary artery caused a gradual swelling of the left auricle, which was distended until it appeared like a bright red, shining bladder, its rhythmical contraction lessening to an oscillating movement, which finally ceased. This phenomenon was observed when the left ventricle was weakened and its action retarded, while the right auricle and ventricle continued to contract strongly. As soon as the compression was stopped and the left ventricle began again to contract, the distended auricle emptied itself in one to two minutes, and both sections of the heart were again in uniform action. This phenomenon constitutes a striking illustration of the mechanism by which obstruction at the mitral orifice or weakness of the left ventricle leads to auricular dilatation and to œdema of the lungs.—*The Lancet*, June 19, 1880.

Case of Perforation of a Round Ulcer of the Stomach into the Left Ventricle of the Heart.—Prof. Chiari presented the specimens illustrating this accident to the *Vienna Medical Society*, in May last. The patient, a woman, seventy-one years of age, had died shortly after her admission to the hospital. The symptoms were hematemesis and passage of blood from the intestines, and the clinical diagnosis was ulcus ventriculi. At the autopsy a round hole two centimetres in diameter was found in the lesser curvature of the stomach. This opening led into a sac as large as a walnut, formed by cicatricial tissue; the sac extended through the diaphragm, pericardium, and wall of the left ventricle of the heart, and presented at its apex an ulcerative opening large enough to admit an ordinary probe into the left ventricle. The heart was closely adherent to the pericardium over a space eight centimetres square; the mitral, tricuspid, and aortic valves were thickened at their free edges; the muscular tissue of the heart was pale and friable, and had undergone moderate fatty degeneration; the endocardium was thickened for a distance of one centimetre around the perforation. The stomach and intestines contained a large quantity of fresh blood. The body generally was very anæmic. In the wall of the sac, close to the opening into the stomach, a hard, brittle mass, two millimetres long and about one millimetre thick, was found. Chemical examination showed that this particle was composed chiefly of silicates, and it was probably a piece of glass that had been accidentally swallowed at some time. Dr. Chiari attributed no special importance to this foreign body, as he thought that it had merely found a lodgment in the sac subsequent to the formation of the latter. He stated that he had been unable to find in medical literature any analogous case of the opening of a round ulcer of the stomach into the cavity of the heart.—*Allg. med. Cent. Zeit.*, June 9th.

Iodoform in Affections of the Eyes.—M. Hayer states that iodoform is a very valuable remedy in the treatment of certain subacute and chronic affections of the eye and the eyelids. It has been employed with advantage, particularly in the treatment of granulations. He recommends it also for ulcers of the cornea, obstinate keratitis, etc. The fine iodoform powder should be applied directly to the affected spot by means of a hair-pencil. For application to the lids he uses a salve of one part iodoform to four parts vaseline. The iodoform causes no pain, and can therefore be employed without difficulty in the case of children. The remedy is useless during the watery stage of conjunctivitis.—*Allg. med. Cent. Zeit.*, June 9, 1880.

Gaultheria in the Treatment of Purulent Cystitis.—M. Perier recommends the essence of wintergreen as a local application in cases of purulent cystitis. This essence is a powerful antiseptic, but it has the disadvantage of being very insoluble. M. Perier employs the following solution: essence of wintergreen, 6 grammes; tincture of quillaya saponaria, 30 grammes; water, 1 litre. He uses this solution freely for washing out the bladder, with excellent results, and also as a wash for wounds, and for simple dressings. He also combines one part of the essence with one hundred of vaseline, and uses it to anoint his instruments, and often for his hands, in antiseptic operations.—*Journal de méd. et de chir.*, May, 1880.

Restoration of the Hand after it was almost Completely Separated from the Arm.—Dr. Staton, of North Carolina, reports the case of a girl, eleven years of age, whose hand was almost completely severed from the arm by a blow with an axe. The wound extended obliquely through the carpus, and all the muscles, bones, and blood-vessels were divided, the hand remaining attached to the arm only by a small strip of skin below the articulation with the ulna. Dr. Staton saw her about thirty minutes after the accident, and found the hand hanging at right angles to the arm. He determined to amputate at once, but abandoned this intention because of his inability to procure assistance. After some delay occasioned by this change of plan, he replaced the hand, and secured it in position with silver wire sutures and adhesive plaster. The child complained of pain when the needle was used in the arm, but not when it was used in the hand. The hand and arm were then secured on a broad splint, and kept warm by being wrapped in hot flannel cloths. Twelve hours later the hand was very much swollen; no sensation or pulsation could be detected; the patient had complained of no pain, and had rested quietly during the night. On the next day she complained of a little pain, but the hand and arm presented the same appearances. On the third day the hand had changed color, and pulsation could be detected in it. From that time the patient did not have a bad symptom. There was no suppuration, the wound healing entirely by first intention. The sutures were removed on the fourteenth day, and the hand placed in a sling. Within three months after the accident the patient could extend the fingers, and grasp with nearly the usual strength. No anchylosis of the wrist-joint resulted.—*Medical and Surgical Reporter*, June 19, 1880.

TREATMENT OF PROLAPSUS ANI IN CHILDREN.—Dr. Basevi (*Giornale Internazionalle delle Scienze Mediche*, Fasc. 9) employs the following treatment in chronic cases of this affection. He first cauterizes lightly the protruding portion with nitrate of silver and then reduces it, administering afterward, with the view of checking any tendency to enteritis, an enema of tannic acid, alum, and ice-cold water. Should this treatment prove insufficient, the child is placed on a bed with the nates upward, and steadied by two assistants, one of whom fixes the upper part of the body while the other holds the knees elevated and somewhat abducted. The prolapsus having been reduced, the nates are brought together, and two strips of diachylon plaster, each about two inches wide, are passed from one trochanter to the other in as close proximity as possible to the perinæum. To keep them in place, a spica bandage is applied around the lower portion of the body, and a piece of guttapercha is added to protect the plaster from the contact of fæcal matter. The apparatus may be left in position for two weeks.—*London Medical Record*, June 15th.

INJECTIONS OF MORPHIA IN INTESTINAL OBSTRUCTION.—One grain of morphia injected subcutaneously three times a day, in a case of intestinal obstruction which lasted for thirty-nine days, met with excellent results at the hands of Dr. W. H. Lambert.—*London Lancet*, June 26, 1880.

A NEGLECTED SYMPTOM IN BREAST-CANCER.—Dr. Herbert L. Snow, Surgeon to the Cancer Hospital at Brompton, England, calls attention to a symptom which very commonly occurs in the course of breast-cancer, and on which sufficient stress has not been laid. He refers to a thickening of the humerus on the side corresponding to the diseased gland, accompanied by tenderness on pressure. This condition obtains mainly over the trochanters and the upper third of the bone. On firm pressure the patient complains of tenderness, which extends for a variable distance down the shaft, beyond the part where thickening is apparent. The movements of the arm are rarely interfered with, and the tenderness and thickening are never noticed by the patient before examination; they are only detected by digital pressure and comparison with the humerus on the opposite side. Occasionally there is some thickening of the clavicle. The condition never advances to any very marked hypertrophy. Dr. Snow regards the "thickening" as due to a low form of periostitis, consequent upon deposit of cancer-germs in the medulla.—*London Lancet*, June 12, 1880.

MORPHINE AS AN ANTIDOTE TO DATURINE AND ATROPINE.—Dr. Strömberg reports the case of a child of five years, who was almost fatally poisoned by eating the seeds of the datura stramonium, the alkaloid of which is very closely allied to atropine. Three other children, between the ages of three and seven years, ate the seeds at the same time, but in them the symptoms, though severe, were not alarming. The first child had an exceedingly rapid, thready pulse, stertorous and very irregular respiration, and almost continuous clonic spasms, which were so violent that his body was tossed about in the bed. At frequent intervals he uttered a hoarse, inarticulate cry. The pulse gradually became irregular, the other symptoms remaining the same. Death seemed imminent, and morphine was resorted to as a last hope. One-third of a grain, divided into three doses, was injected subcutaneously within the space of an hour. After the first injection the pulse became fuller and less rapid, and the respiration soon began to improve. The spasms became less constant, the intervals between them rapidly increasing in length, and after two hours all danger seemed to be over, although the patient continued restless for several hours, when he finally fell into a quiet sleep. Dr. Strömberg thinks that the morphine undoubtedly saved the child's life, and that the case demonstrated the existence of an antagonism between morphine and daturine. This conclusion is fortified by the fact that the dose of morphine, though very large for a child of that age, did not produce sleep.

Dr. Leder reports the case of a girl, seventeen years of age, who took by mistake five ctgrms. (five-sixths of a grain) of atropine in one dose. He saw her eight hours later and found her exceedingly restless, and constantly trying to get out of bed. She knew no one, paid no attention to calls, and seemed to be suffering from pain and to be worried by hallucinations. The pupils were very wide and the eyeballs prominent. The respiration was very rapid, the pulse 150 in the minute, and the voice tremulous. An emetic was administered with much difficulty, and 0.007 morphine (about gr. $\frac{1}{8}$) was injected subcutaneously every twenty minutes. After the second injection the delirium began to diminish, and after the fourth the patient fell asleep. The pulse was then 110, and the respiration 17. After three hours' sleep the patient awoke in the full possession of her senses. Convalescence was rapid.—*Berliner klin. Wochen.*, July 5, 1880.

ATROPINE AS AN ANTIDOTE TO MORPHINE.—A case of poisoning by the hypodermic injection of morphine was recently observed in the medical clinic in Halle. The patient, an adult man, was deeply cyanosed, especially his face and hands, and profoundly comatose. The respiration was very slow, the pulse slow, weak, and irregular, the temperature in the rectum 97°, and the pupils were excessively contracted. Artificial respiration by methodical compression of the thorax was immediately resorted to, and one milligramme of atropine was injected. Half an hour later, as the patient's condition was unchanged, ten milligrammes of atropine were injected at a dose. Fifteen minutes afterward the cyanosis had disappeared, and the pulse was more regular, although still only 40 in the minute. During the next twenty minutes, ten milligrammes more of atropine were injected in different parts of the trunk, the artificial respiration being still kept up. Ten minutes after the last injection the pulse was 60, and the pupils had regained their normal width; in an hour and a half the pupils were dilated to the maximum, the heart-sounds were clear and free from murmurs, and the pulse was 80. The coma still persisted, but it now began to diminish gradually. On the following morning, twelve hours after the administration of these immense doses of atropine (twenty-one times the maximum dose in Germany), the pupils, pulse, and respiration were normal. The patient said he had no headache, and complained only of formication in the fingers and toes. A few hours later the mydriasis returned, and it now persisted for several days. The patient was formerly an opium-eater, but had been compelled, by want of money, to do without opium for the two or three years preceding this attack of acute poisoning. On this occasion he had accidentally got hold of a solution of morphine, and took at once six injections containing 0.28 morphine (gr. 4⅓). The amount of the antidote employed in this case was one-thirteenth of the amount of the poison taken.—*Berliner klin. Wochen.*, July 5, 1880.

Coffee as an Antidote to Strychnia.—D. Attilio Lilli reports a case in which a large dose of strychnia was taken in coffee without producing any toxic effects. The case led him to experiment with these drugs on rabbits, and he found that the coffee acted as a perfect antidote to the strichnia, completely annihilating its toxic action, or, at all events, notably diminishing the violence of its action.—*La France médicale*, July 7th.

Fibromatosis, or General Hyperplasia of the Connective Tissue.—Under the name fibromatosis Professor Beneke, of Marburg, describes a peculiar constitutional anomaly, which is characterized by a great tendency to connective-tissue hyperplasia in the different organs of the body, and which is more closely allied to the constitutional anomalies resulting in hyperplastic new-growths than to the phthisical process, although it often presents itself under the form of pulmonary phthisis. These cases of phthisis pulmonum are characterized, even after death, by the powerful build of the body, the marked development of the panniculus adiposus, and the blood plethora, all of which contrast strongly with the destructive process in the lungs, as well as with the external appearances in cases of ordinary phthisis. The changes in the lungs in these cases are very various, but they all seem to begin with hyperplasia of the connective tissue. In some cases the lesions consist chiefly in a marked thickening of the interstitial connective tissue, the contraction of which leads to atrophy of the pulmonary tissue as the result of compression, and to irregular dilatations and contractions of the larger bronchi. In such cases often no traces of caseous degeneration of the new-growth can be found. In other cases the interstitial connective-tissue hyperplasia is less predominant. The bronchial dilatations are larger, and bronchiectatic cavities are developed, in the neighborhood of which more or less numerous fatty and caseous masses are found. In still other cases these lesions are found, perhaps, in the upper lobe, while in the lower lobe miliary tubercles or peribronchitic caseous nodules are met with. Between these forms and true caseous desquamative pneumonia there is no other intermediate form. For both classes of cases the clinical diagnosis must be pulmonary phthisis. The pleuræ usually present large thickened areas. The liver, kidneys, and spleen are usually hard in consequence of extensive growth of the interstitial connective tissue; the heart is, as a rule, hypertrophied.

Now, Prof. Beneke believes that, just as there is a general hyperplasia of the adipose, the bony, and the epithelial tissues, so there is in these cases an analogous hyperplasia of the fibrillar connective tissue of the body, resulting from some obscure modifications of the general constitutional condition and the nutritive changes. These modifications, probably, differ but little from those which lie at the bottom of the known hyperplasias just mentioned. This theory finds a support in those cases where the pleuræ and peritoneum are studied with countless nodules, varying in size from a millet-seed to a pea, which resemble, at first sight, miliary tubercles, but are shown by microscopic examination to be minute fibromas. Prof. Beneke would also cover with the mantle of fibromatosis those cases of pachymeningitis in robust individuals, where death results from interstitial nephritis, and where, at the autopsy, connective-tissue hyperplasias are also met with in the lungs, serous membranes, liver, etc. Further, the granular kidney, in robust individuals, which has been so much spoken of in late years, likewise belongs, in all probability, in the same class; this would harmonize well with Buhl's theory, that the connective-tissue thickening in the serous membranes, heart, and lungs, is the result of a "fibrous inflammation."—*Deutsche medic. Wochen.*, July 17, 1880.

Occipital Headache as a Symptom of Uræmia.—Recent observations on the symptomatology of Bright's disease disclose the fact that severe pain located in the occiput may be regarded as one of the symptoms of the disease. Dr. E. C. Seguin has recently met with two cases (*Archives of Medicine*, August, 1880) in which occipital headache was so localized and persistent, as to give rise to a strong suspicion of organic disease of the cerebellum. In one case a positive conclusion was only reached by means of a post-mortem examination, which showed that the cerebellum and the other parts of the encephalic mass were normal, while both kidneys were extensively diseased. The left kidney was found completely diseased, granular and hard in places, its membranes peeling off with difficulty. It had a reddened, congested appearance, and showed evidences not only of a chronic trouble, but also of a more recent acute inflammatory action. The right kidney was found to be only partially affected—somewhat congested, and with the same type of lesion. These cases both now appear to have been examples of contracted kidneys and uræmia. Both patients were adults, had suffered from chronic headache, more or less of the migraine type; at a given period the headache became transformed into a localized occipital pain very different from the former attacks. The symptoms of renal disease were not marked; in one case there was no œdema, in the other a mere trace; neither patient had the dyspeptic symptoms or the frontal headache which often suggests renal disease, and neither patient had the "Brighty look" which is so well known. The occipital sensation in these cases was true pain, not the painful paræsthesiæ which are sometimes due to lithæmia and oxaluria, and sometimes to eye-strain, and which are erroneously (or rather insufficiently) designated as cerebral hyperæmia. In Case II. the pain extended down the cervical spine, and was so much aggravated by movement as to suggest a rigid state of the neck. In Case I. there was once stiffness of the neck in an attack. This peculiar headache was distinctly paroxysmal, but not at all periodical or influenced by any apparent outward circumstance. In both cases nausea accompanied the headaches, and in Case II. it is clearly stated that the nausea was secondary in point of time. Case I. was made relatively clearer by the previous history of convulsions and albumen in the urine.

Dr. Seguin is inclined to believe that the publication of these cases may serve to render more accurate the diagnosis of occipital headache, and to illustrate the utility of critically examining the urine in cases of any degree of obscurity, more especially as occipital headache is scarcely mentioned as a symptom of uræmia.

A Rare Form of Uterine Hemorrhage.—A rare case of uterine hemorrhage is reported by Henry Gorst, house surgeon of the Lying-in Hospital, Liverpool, in the *British Medical Journal* of July 3d. Patient, æt. 28, after a natural labor, got up on the ninth day, and went about her household duties. Seven days afterward, she was taken with a profuse hemorrhage, which was controlled by plugging the vagina and rest in bed. No hemorrhage followed the removal of the plugs. Three days after the removal, hemorrhage recurred so profusely as to leave her in a state of collapse. She was again plugged by another surgeon, and the hemorrhage ceased. On the following day she was removed to the hospital, the plugs were removed and iron and ergot were administered. She was kept in bed for five days, when she had a sharp attack, losing a large quantity of blood in a very few minutes before she was tightly plugged. In the evening the plugs were removed. The uterine sound showed the uterus to be in its normal position, and its cavity only measured three inches. The external os was patulous, but the cervix was too tightly closed to allow the introduction of a finger; two sea-tangle tents were therefore passed up to the fundus, and kept in position by two good-sized pads of lint in the vagina. An attack of hemorrhage occurring during the night, the tents being in position, led the doctor to suspect that the hemorrhage came from the cervix or vagina. In the morning a Ferguson's speculum was introduced, and on the cervix, just at the lower edge of the posterior lip of the os, a good-sized artery was seen distinctly pulsating. There was some superficial erosion of both lips of the os, but no laceration. There was no hemorrhage now, and the vessel was distinctly seen plugged with a clot. Touching it with a point of a probe soon dislodged the clot, and the hemorrhage again came on *per saltum*, the blood spurting to the middle of the speculum. The vagina was packed slightly and the discharge temporarily arrested. Three days afterward hemorrhage again occurred. The liquor ferri perchloridi and the actual cautery proved ineffectual. The patient was now nearly pulseless, and transfusion was resorted to. Blood not being readily procurable, a pint of Little's saline solution at 98° was injected into the median cephalic vein. Immediately after the injection the pulse, which was previously scarcely perceptible and from 160 to 180 a minute, became considerably stronger and slower. Next day she rallied somewhat, the pulse became more perceptible; slight oozing of blood continued through the plugs; and the vomiting became constant. She continued in this condition until the evening of the following day, when she died. At the necropsy only the pelvic viscera were examined. An artery, equal in size to the ulnar, was found quite patent, at the lower edge of the posterior lip of the os uteri. On dissection it was found to be a branch from the uterine, which produced a loop in the cervix, extending as low down as the edge of the os, and ulceration through it had taken place at the point of bleeding.

Homatropin—A New Mydriatic.—The discovery of homatropin by John Tweedy, F.R.C.S., bids fair to become one of great value and utility in ophthalmic practice. It is a bland but efficient mydriatic; its action is rapid and of comparatively short duration. It possesses many of the properties of atropine, but in a weaker degree. On the heart, however, their effect is very different, for atropine accelerates and strengthens the heart's contraction in man, whereas homatropin slows the beats and renders them irregular in force and rhythm. Though relatively weaker than atropine, its action on the iris and the ciliary is really very powerful while it lasts. The chief peculiarity, and, in some respects, the great advantage of homatropin is, that its effects soon pass off, and certainly do not last near so long as those of atropine. It is also unirritating. Dr. Sidney Ringer confirms the experiments of Tweedy.—*London Lancet*, May 22, 1880.

Changes in the Seminal Fluid in Connection with Gonorrhœal Epididymitis.—These alterations have already been studied, in France, by Gosselin and Godard. Dr. Terrillon has lately given much attention to the subject, and from an analysis of twenty cases he draws the following conclusions: Epididymitis causes changes in the spermatic fluid, both as regards its color and the nature and interproportion of its anatomical elements. Such alterations vary with the phases of the disease. During the acute stage the semen has a more or less decidedly yellowish green appearance, resembling pus. This color is due to the presence of a variable quantity of pus-corpuscles. Large granular globules are also found in some number. The spermatozoa may be absent after the first few days, but in some cases they may be found living and well formed in the purulent fluid, but diminished in number. They may continue to be present for a variable period, and may even persist throughout the course of the disease. The mixture of the pus-corpuscles and granular globules, frequently containing spermatozoa, can only be furnished by the inflamed mucous membrane of the seminal passages, as is shown by its identity with the fluid found in the vas deferens at some autopsies. This fact also shows that a purulent catarrh of the seminal passages takes place in these cases.

After the termination of the acute period of the epididymitis, the same spermatic alterations may still be met with. But the color of the semen is no longer so distinctly purulent, the pus-corpuscles are diminished in number, the spermatozoa are generally absent, and there is a predominance of liquid ingredients. These changes may persist for long periods; sometimes they continue indefinitely long, especially in cases where the spermatozoa fail to reappear. In cases of unilateral epididymitis all these changes are less clearly marked.—*Annales de dermatol. et de syphil.*, July, 1880.

* * *

Perfumed Carbolic Acid is a solution of the acid in alcohol with oil of lemon added. The proportion is: carbolic acid, 1; oil of lemon, 3; alcohol, 100.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 4, 1880.

THE REGULATION OF PROSTITUTION.

CERTAIN statistics were published several months ago, relative to the effect which the regulation of prostitution has upon the population and social condition of countries in which that system is established. The countries especially referred to were France and Belgium. It was shown, first, that prostitutes and concubines were less fruitful than married women, and that the children of the former had less chance of living. The regulation of prostitution, it was claimed, had a tendency to diminish the number of marriages and increase concubinage. The final results were a lessening of the prominence of the family in the state, a lowering of the birth-rate, and a decrease in the population of the country. France and Belgium were brought forward as practical illustrations of this tendency.

The editor of the St. Louis *Clinical Record*, discrediting the accuracy of these conclusions, if not of the statistics, has recently brought out some counter-evidence. He prints tables showing that "regulation" is efficient as a sanitary measure, as shown, especially, by the relative amounts of venereal disease in the English and French armies. He also presents figures showing that the birth-rates in France are not much lower than those in some other countries, notably in Ireland, a country which has a deserved reputation for the chastity of its women. His conclusion is that regulation is an efficient and useful measure, that the alleged decrease in population does not of itself indicate a bad state of affairs, but perhaps the reverse, and that the asserted decrease of families and increase of concubinage is due to other causes than the regulation of prostitution.

While agreeing in part with the views thus advanced, we have been unable to corroborate some of the statistics given to support them; and the importance of the subject warrants an attempt at their correction. In regard, especially, to the question of the sanitary and political benefits of regulation, there are some glaring inaccuracies. A table is given, for instance, in which the number of cases of venereal disease is put down as follows:

English army..............	363 per 1,000
French army..............	103 per 1,000

Now, according to a synopsis made from the British army reports (*Westminster Review*, July, 1876), the proportion of venereal diseases in the British army in 1872 was about 223 per 1,000. The proportion at the present time is somewhat less than this, both in stations where prostitution is regulated by the contagious diseases acts, and where it is not. The proportion given of 363 per 1,000 is that which existed seventeen years ago, and the fact that statistics so old as this are presented throws doubt over the value of the whole tables. In regard to the French army, the ratio, as given by the chief of the Statistical Department, was, in 1874, 103 per 1,000 for the army in general. For that part quartered in Paris and Versailles, it was over 109 per 1,000 instead of 21, and in Algiers 198 per 1,000 instead of 63. These are the figures as given in documents furnished by the French Statistical Bureau.

The facts, then, are briefly these: in the French army prostitution is regulated, and venereal disease exists in the proportion of about 103 per 1,000. In the British army regulation also exists in fourteen stations, and here venereal disease exists in the proportion of about 223 per 1,000; in the other stations the proportion of venereal disease is slightly greater, opinions differing as to how the difference should be considered.

These facts do not show that regulation, as applied to army stations, fails to lessen venereal disease, a thing which we are not disposed to doubt; but it proves that the measure secures no such wonderful results as might be inferred from comparing the figures 106 with 323. Furthermore, we have heretofore taken the ground that the sanitary success of regulation, as applied to armies stationed in garrison towns, gives no proof that such regulation will succeed, or be advisable, from any point of view, in other places. It has seemed to us, from an examination of all the facts accessible, that in nearly all general communities where prostitution has been regulated, its sanitary benefit has been either nothing at all, or has been entirely outweighed by attendant evils.

In regard to the other statements that have been quoted regarding births, marriages, and their relation to prostitution, we have here also been unable to substantiate many of them. The conclusions drawn on each side seem to be premature. France, for instance, does have the smallest birth-rate of any European nation, but she has had this most of the time for one hundred and fifty years, while regulation proper began in Paris in 1823. This birth-rate, though lower than it was fifty years ago, is not decreasing now, or was not up to 1878. In 1868 it was 26.2 per 1,000; in 1875, 26.4 per 1,000. The surplus of births over deaths in 1877 amounted to several thousands.

Again, in Belgium the population is very far from diminishing in number. From 1830 to 1877 it increased yearly at the rate of one per cent. The surplus of births over deaths has also steadily increased, and was, in 1877, 60,808, in a population of five millions. It is not possible for any changes to have occurred since 1877 that could be relied upon as indicating a permanent difference in the tendency of the population. And so far the facts seem to agree with the views of the *Clinical Record.* We have, however, to correct one other error in that generally accurate journal. It gives in a table the proportion of births per 1,000 women in several European countries. It finds that of Ireland to be 114 per 1,000, which is almost as low a rate as that of France; and the inference is considered probable that birth-rates are not lessened by the prevalence of licensed prostitution. Now the birth-rate thus assigned to Ireland is not correct, but is only the approximate estimate given in making up the returns of vital statistics. In the various numbers of the *Journal of the Statistical Society,* where these figures are quoted, an editorial note is always appended stating that the rates of births, marriages, and deaths, as reported, are smaller than is actually the case. No conclusions can be drawn, therefore, from the vital statistics of Ireland.

On looking over the statistics of countries in which regulated prostitution exists, however, there are two things which strike one, and these sustain somewhat the theory of the evil effect upon a nation of regulating prostitution. Thus, for example, in Belgium the number of marriages is yearly decreasing; and in France the number of illegitimate births is yearly increasing and is greater than in unregulated countries like Great Britian. In Belgium, the number of marriages in 1873 was 40,598; that in 1877 was 36,962, the population meanwhile increasing. In France, the proportion of illegitimate to legimate births in 1815 was 1 to 20; in 1877 it was 1 to 14. The proportion in Paris now is 26.75 illegitimate to 100 legitimate births. In London it is 5.75 to 100. In the Department of the Seine, the proportion of illegitimate births in 1877 was 25.21 per cent. In Scotland, on the other hand, the proportion in 1878 was 8.5 per cent.

We are far from assuming that the regulation of prostitution is the sole cause of the above differences. But it is one of the factors in it, and these differences mean a great deal. A decrease of marriages and increase of illegitimate births implies a weakening of domestic ties and a diminution in the importance of the family as a social unit. Upon the integrity of the family rests the strength of the nation.

It is not such questions, however, that we are called on to discuss, and we wish now only to bring out the fact that doubts hang over the political expediency of regulating prostitution. As to its sanitary efficacy we can speak more strongly and with greater confidence. It is only under certain conditions that the sanitary benefits have justified the adoption of regulation in any of its present forms. We add here a little evidence on this point. The municipal government of Zurich, in abolishing regulation in 1874, said: "The opinion that tolerated houses are a preservative against contagious diseases is refuted by modern statistics, and supported at present only by a minority of opinion among the faculty, and by the tenacity of inveterate prejudice." A similar opinion is given by Dr. Castiglioni who was government inspector charged with applying the *regulations at Rome.* The reports of M. Le Cour, chief of the Bureaux des Mœurs, of Paris, have the same tenor. The fact that now, after more than twenty years of vacillating policy, the open recognition of licensed houses is at an end throughout the German Empire, confirms this view that regulation, as it has been carried out so far, is an inadequate sanitary measure.

ALCOHOL IN HOSPITALS.

THE report of a committee formed at St. George's Hospital to ascertain the comparative use of alcohol in the large London hospitals, together with some recent reports from the London Temperance Hospital, have drawn attention to the subject of the amount of alcoholic liquors proper to be given to the sick, and especially to hospital patients. The experience of the London Temperânce Hospital in this matter is the most unique, and deserves to be widely known. This hospital, in the past eighty months of its existence, has treated about nine hundred in-patients and eight thousand out-patients entirely without the use of alcohol, even in the medicines. The principles on which the institution is conducted are:

1. That alcohol shall not be given as a beverage; 2, that it shall not be given in medicines in the form of tinctures; 3, that it shall only be administered as a medicine and upon a written prescription of the physician. Practically, it has not been found necessary to prescribe alcohol at all. The tinctures used are made with glycerine instead of alcohol; and this, by the way, is a practice that will, no doubt, eventually be largely adopted by pharmacists, since glycerine is a better preservative and ensures more uniform strength. The cases treated in the hospital have been of ordinary severity. A number of amputations have been performed, as well as ovariotomy, Cesarean section, ligature of the common carotid, etc. The mortality has only been 4½ per cent., which is certainly a very good showing. There were three classes of cases among the out-

patients which are generally treated with alcohol, but which were not given any in the present case. These were cases of phthisis, cases of indigestion, and cases of general debility from overwork or underfeeding. No statistics are given to show exactly how these patients got along without alcohol; but we are assured by the medical officer that he never in any instance found that it was necessary to prescribe it.

The report of the St. George's Hospital committee gives figures which indicate a very large, and, it would seem, excessive use of alcohol in the majority of the London hospitals. It should be remembered that it is the custom in most of these institutions to give out beer as part of the regular diet. We find that in St. Bartholomew's Hospital, which treated 5,868 patients in 1878, the cost for liquors was about $5,700. In the Middlesex Hospital where 2,040 patients are annually treated, $2,700 is spent for alcohol. At Guy's Hospital, the figures are: patients, 5,710; annual cost for liquors, $5,000. On an average, the London hospitals pay from eighty cents to a dollar per patient for liquors. In only two or three hospitals are the sums expended very small. At Westminster Hospital 1,763 patients are treated, at an annual cost for liquors of less than fifty cents per patient; and at St. George's Union Infirmary 2,496 patients were treated in 1878, at a total cost for wine, beer, and spirits, of about $40.

In most of our New York hospitals the cost per patient for liquors is from a quarter to a third less than it is in the London institutions. Thus, in Bellevue Hospital, where liquors are prescribed without stint, when thought necessary, 5,986 cases were treated in 1878, at a cost of $2,982.42; in Charity Hospital, in 1878, the patients were 8,574, the cost for liquors $3,109.02. Among our endowed hospitals there is a great variation in the amount of liquor consumed. Roosevelt Hospital and the Massachusetts General Hospital present, perhaps, the two greatest extremes. In the former 1,617 patients are treated annually, with an expenditure for liquors of $719.13. In the latter the liquor bill for its 1,813 patients is $2,070.60. If anything at all is shown in these figures, it is that alcohol is, as a rule, given much more indiscriminately and extravagantly in hospital practice than is at all necessary. When a dozen hospitals report about the same mortality rates whether they pay a cent or a dollar and a quarter per patient for alcohol, there can be but one conclusion drawn. The temperance or semi-temperance hospitals of London have helped to show this if they have done no more. Despite the better showing which most of our hospitals make, we believe that much more alcohol is given than is at all necessary. The blind faith in the potency of alcohol as a stimulant, whenever the pulse gets weak or the lungs begin to rattle, has sometimes a pernicious result. The administration of alcohol as a tonic is attended with risk and uncertainty. There should be greater judgment and greater economy applied in prescribing what may be a potent remedy, a dangerous poison, or simply a useless and expensive beverage.

Reviews and Notices of Books.

WOOD'S OPHTHALMIC TEST-TYPES, EXPLANATORY TEXT TO, AND COLOR-BLINDNESS TESTS. By G. R. CUTTER, M.D., Surgeon New York Eye and Ear Infirmary, Ophthalmic and Aural Surgeon St. Catharine's and Williamsburg Hospitals, etc., etc. New York: Wm. Wood & Co. 1880.

IN a very compact form we have all the necessaries for a complete testing of the refraction of the eye and also the color sense.

In a box 24 × 10 are the following materials, viz.: eleven plates, ten of which are test-plates; plates Nos. 1 and 3 (Snellen's) for distant vision; plate No. 2 (Snellen), arranged for those unable to read, used for distant test; plate No. 4 (Snellen) for near vision; plates Nos. 5 and 6 (Jaeger) for near vision; plates Nos. 7 and 8 (Wecker), tests for detection of astigmatism; plate No. 9 (Green), dial test for astigmatism; plate No. 10, test for astigmatism and for detecting the equilibrium of the muscles; plate No. 11, illustrating the mistakes of the color-blind, after Holmgren. Then we have four concave and four convex lenses for testing various degrees of refraction; these few lenses are amply sufficient, as by combining them a large variety of changes can be obtained. No cylindric lenses are given; but a stenopaic slit, by means of which the amount and degree may be determined, as explained in the text. Next, we have a holder with three grooves to fix the glasses in position, the arrangement of which is simple and new. Then come one hundred skeins of Berlin worsteds (Holmgren's test-skeins) for determining color-blindness, the test-skeins marked with tags so that no mistake can be made.

Then we have the most important of all, the "Explanatory Text," by Dr. Cutter. A more competent ophthalmologist could not have been chosen; in fact, one wonders how he could condense the whole subject so clearly and definitely in fifteen pages, —six of which are devoted to color-blindness—which has assumed so much importance of late.

The text begins by explaining the principle upon which Snellen made his test-types, and then proceeds to show how to record vision accurately. Then an explanation of what is hypermetropia, myopia, presbyopia, and astigmatism. An explanation of the trial-glasses follows, with an approximate equivalent of the old and new (dioptric) systems, with a table of combinations that can be made with the glasses.

The last six pages are devoted to "Color-Blindness," giving the Young-Helmholtz theory, with four figures illustrating it. Finally, the book concludes with Holmgren's directions for using the test-skeins.

We are certain that this case will meet a need long felt, especially among the busy practitioners who often want to determine whether the patient has any organic disease or only some refractive trouble—and with this inexpensive case he can readily do so—and, as is stated in the preface, it is "to enable the family physician to decide whether his patient requires the special services of an oculist."

In conclusion, we congratulate Dr. Cutter on his having done his part so well, and William Wood & Company on their new venture.

Transactions of the American Gynecological Society. Vol. IV. 1879.

It is naturally with some diffidence that we approach the criticism of a work prefaced by the announcement that "the reviewing of medical literature is, in this country, in a condition of deplorable fatuity;" and any self distrust thus aroused could not fail to be increased by the impressive elegance of green and red and gold in which the volume before us appears. The book looks too unspeakably genteel for any criticism, fatuitous or profound. It would be a tasteful addition to the bric-a-brac of a lady's boudoir, or to the Kensington needlework of a Fifth Avenue parlor. And he is a monster who would not treat so effulgent a piece of workmanship with tenderness.

Its contents have been given to the public quite fully in previous numbers of the Record. No extended analysis, therefore, will be required now. But we will venture to discuss some of the points made in the addresses and papers; and if we criticise with fatuity, it shall not be with ignorance or dishonesty.

Dr. Thomas's address on "The Gynecology of the Future and its Relations to Surgery" is suggestive and striking. We venture to say, however, that if some of the distinguished orator's ideas are stripped of the pleasing rhetoric in which they are clothed, they will appear decidedly *naïve*, to say no worse. Dr. Thomas complains of the injury which the spirit of dogmatism has caused to his specialty. He makes the complaint with justice, but he does not go to the bottom of the question. Dr. Thomas ascribes this dogmatic spirit, and most of the consequent imperfections of gynecology, to the difficulty in, and lack of, clinical teaching; and he would have a gynecologist attached to every general hospital, who should operate and expound before the general public. Now, this plan might be occasionally useful; but that it would be the cure-all for gynecological idiosyncrasies, is absurd.

It will occur to those at least who are not professed gynecologists, that this specialty needs more mental equipoise, not to say actual brain-matter, quite as much as it does more clinical opportunities.

It is a fact in general medicine and surgery that, where different men obtain astonishing results in the same disease only when they use their own particular measures, these men are either crafty or foolish, or the disease goes its course without regard to them. Why things should be different in gynecology it is hard to see.

We have occasional gynecological clinics in this city, but they do little more than satisfy the curiosity of first-course medical students. That they should bring harmony into the treatment of the displaced womb or the diseased cervix is beyond the dreams of anything but inordinate faith.

Another remedy suggested for the vagaries of gynecological therapeutics is the establishment of a kind of gynecological literary bureau, which shall pass in searching review all the contributions to its department of quasi-science. Now, gynecology has some good men and true, as Dr. Thomas asserts; but how, alas, shall we know who they are? Shall it include those who, following the motto of their Society—

"Ohne Hast
Aber ohne Rast,"

stitch and stitch the cervix, or of those who cut it off; of those who medicate the endometrium, or of those who send its owner to Europe; of those who slit the cervix, or of those who plug it with tents, or of those who denounce both measures? Shall there sit upon this gynecological Parnassus, pessary men or anti-pessary men; and, if the former, what kind shall be used, and how far up shall they be advised to extend, in criticisms not "deplorably fatuitous." Would this bureau advocate the knife or constitutional treatment the more; would it be a spaying or an anti-spaying organization? And would they advocate kolpoecpetasis or kolpokleisis? We confess that we await with impatience the work of this prospective body which is to create an era in the reviewing of medical literature.

Dr. Thomas briefly goes over the history of gynecology, and, with a masterly comprehensiveness not unworthy of Buckle, strikes the key-note of its recent rapid progress. This particular note is the discovery of anæsthesia. The point is worked out with much eloquence; but indeed we have heard of this discovery before, and it would be a relief to read an an annual address that did not refer to it. The discovery of anæsthesia has been the backbone of annual addresses for so many years that he who introduces it now must consent to be accused, if not of fatuity, at least of vacuity of presentable ideas. Besides, there are other important causes of the popularity of gynecology which the orator forgot. One of these is the women themselves. Not especially women as owners of the organs that have been so vigorously experimented with in the last fifty years, but women as possessors of that peculiar mentality which makes them like to see and be treated by "their own doctor," and to believe themselves victims of the different fashionable diseases of their sex. Women have thus given an impulse to gynecology which should be duly acknowledged.

We have made these few criticisms upon Dr. Thomas's address because they seemed to be demanded by the honest criticism of which gynecology, as he admits, is so much in need. We have not a great deal to add in regard to the other articles in the book. Dr. White's and Dr. Battey's papers, on Intra-uterine Medication, are very good pleas for a plan of treatment that was but half endorsed in the subsequent discussion. The papers on Intra-uterine Injections, by Drs. Jenks and Chadwick, present measures for the treatment of septicæmia already quite widely known and adopted. Dr. S. C. Busey's paper on the Pathology of the Cicatrices of Pregnancy was too learned and scientific for the Society, which fatuitously passed it by without discussion. Dr. Mundé's paper on Prolapse of the Ovaries has been already widely discussed, and is an excellent contribution to a comparatively new subject. The same may be said of Mr. Spencer Wells's report of his case of Battey's operation. Dr. John Byrne advocates the galvano-cautery for kolpocystotomy, in a paper on that subject. Dr. A. D. Sinclair presents some facts in regard to the subinvolution of the uterus, which are new and instructive. Dr. Isaac E. Taylor defends the use of the forceps in the first stage of labor in certain cases. Papers by Dr. Wm. Goodell, on Clinical Notes on the Elongation of the Cervix Uteri; by Dr. Jos. Taber Johnson, on Mismanaged

Labor; by Dr. J. C. Reeve, on A Case of Extra-uterine Pregnancy, with Successful Application of Electricity, follow. Dr. Ely Van de Warker, in a paper on The Relations of Symptoms to Versions and Flexions of the Uterus, shows that there are no specific symptoms of versions or flexions of the uterus. His conclusions, on the whole, rather throw discredit upon the neat little tables of symptoms which Dr. Thomas embodies in his descriptions of each particular displacement. Dr. Byford describes his method of gradual reduction of a chronically inverted uterus, in a paper on that subject. Dr. W. T. Lusk does the best he can to make the very uninteresting subject of the justo-minor pelvis attractive. Plates, and the history of the case are given.

Dr. Nathan Bozeman writes with intolerable diffuseness on the subject of Kolpocepetasis versus Partial Kolpokleisis.

A new method of performing decapitation is given by Dr. W. L. Richardson; some cases of atresia vagina are given by Dr. Isaac E. Taylor, with remarks upon treatment.

The volume closes with a biographical sketch of the late Dr. Marmaduke B. Wright, by Dr. Theophilus Parvin. The book, as a whole, will take a fair rank among society proceedings. But it comes very far from having a value which would compensate for its extremely dandified appearance.

THE BLACK ARTS IN MEDICINE, WITH ANNIVERSARY ADDRESS. By JOHN D. JACKSON, A.M., M.D. Edited by L. S. MCMURTRY, A.M., M.D. Cincinnati: Robert Clarke & Co. 1880.

"THE Black Arts in Medicine," which is the title of one of the addresses making up the neat volume before us, was first published several years ago for private distribution. The talented author, since dead, embodied in an address before a local society a letter from an old practitioner to a younger brother detailing the manner in which the latter should get into practice, by the exercise of what he pleases to call the "black art." In the easy and pleasant corresponding style he brings the reader face to face with the many little tricks resorted to by the pushing practitioner, and proves how easy it is to gull the public. Starting with the assumption that "the chief end of the doctor is to get practice," he is inclined to make everything bend to it, including the little brains which are necessary to that end. The whole principle of this sort of success, in our author's estimation, is comprised in seizing the many chances which present themselves to the wide-awake man of blowing his own horn or in having it blown by some of his friends.

It would be impossible to follow our author through all the phases of sharp practice which may be resorted to; suffice it to say that the ground is gone over so thoroughly that nothing more in that direction seems to be desired. Its manner of presentation is masterly in its way, and reflects great credit upon the author's ability to present a repulsive picture in an amusing light. We have experienced a rare pleasure in the perusal of the volume.

NASO-PHARYNGEAL CATARRH. By MARTIN F. COOMES, M.D. Louisville, Ky.: Bradley & Gilbert. 1880. 8vo, pp. 160.

OUR author states in his preface that at the request of numerous friends he reluctantly undertook to write a treatise on naso-pharyngeal catarrh, for the use of general practitioners. That he must have consented to do so in a weak moment is not only apparent by the character of the work but by the acknowledgment on his part that "the task" was of "uncertain value." He has probably, as he presumes, satisfied the demands of his friends, who, by the way, will very properly and generously appreciate his endeavors, but it is quite a different thing when he branches out to teach the general practitioner anything new in the treatment of a "class of diseases so commonly regarded as necessary evils supposed to be irremediable."

The work is very elementary in character, contains nothing original, and is carelessly written. Aside from this, the names of many of the authorities are misspelled and their views misinterpreted. These errors admit of no excuse from one who wishes to be considered as an expert, and as one competent to teach his less favored brethren.

The methods of treatment, both local and general, are those usually accepted by the mass of the profession, and the reader will receive no enlightenment as regards the curability of the disease save that the experience of the author in that particular is quite exceptionally good. There is a looseness of expression on his part concerning cures made with ordinary applications which is somewhat startling to the mass of unbelievers. As usual with this class of works the main illustrations are those of instruments, which at best are badly printed, and most of which are so well known that their omission could easily be overlooked.

TRANSACTIONS OF THE INDIANA STATE MEDICAL SOCIETY, 1880. Thirteenth Annual Session. Indianapolis: Carlon & Hollenbeck. 1880. 8vo, pp. 362.

NOT long since we noticed the proceedings of this Society in full in the RECORD, and the fact that a printed volume makes its appearance so soon afterward shows a promptness on the part of its Committee of Publication which is worthy of imitation. The volume, as a whole, presents a very creditable appearance, contains many papers of practical value, with an admirable shorthand report of the discussions. The president of the Society, Dr. J. R. Weist, of Richmond, Ind., leads off with a scholarly and comprehensive address upon the several problems in relation to the prevention of disease. His wide grasp of the subject, and his sound views upon the causes of disease and their prevention, deserve more than a passing notice. Unlike addresses of its kind, it is full of thought, and contains many practical suggestions bearing upon the subject of which it treats. The relation of pauperism, crime, and insanity to preventable disease, and the strange influences of heredity, are presented in a thoroughly practical manner, and must be read to be appreciated.

It may not be amiss, in this connection, to state that more than the usual number of papers were devoted to subjects pertaining to state medicine, and are, almost without exception, first-class productions. Among such of these as deserve especial mention are the articles by Drs. E. J. Van Vorhis, J. D. Gatch, J. W. Hervey, and T. M. Stevens. Dr. Commons contributes a suggestive paper on the use and abuse of ergot, and Dr. Haymond discourses pleasantly upon the always interesting topic of human longevity. With the exception of three or four more papers on general subjects, all the remainder were upon uterine topics. The obituaries are very tastefully enshrouded in black-margined pages, although there is somewhat of a sameness in their composition, and quite a remarkable uniformity in the appearance of a verse of poetry at the end of each.

The constitution and by-laws of the Society appear at the end of the volume, as usual, together with a list of the members of the different counties throughout the state. The volume is neatly published, and is of the average size of those which have appeared during the last three or four years.

FRACTURE OF THE PATELLA; a Study of One Hundred and Twenty seven Cases. By FRANK H. HAMILTON, A.M., M.D., LL.D., Surgeon to Bellevue Hospital, etc. New York: Chas. L. Bermingham & Co. 1880. 8vo, pp. 106.

PROF. HAMILTON, in the present brochure, has collected one hundred and twenty-seven cases of fracture of the patella, fifty-four of these having been under his special treatment. With characteristic care he has analyzed the points of interest in each case, and has summarized his conclusions in his usual impartial manner. As a contribution to the literature of the subject it is of rare value, as presenting the views of the highest authority on fractures in this or any other country. Some of the points which attracted our author's attention are worthy of consideration, as giving a fair idea of the causes, methods of treatment, and results of this interesting form of fracture. These points may be briefly summarized as follows: In a very large proportion of the cases the fracture was transverse, and was caused by muscular action. The frequency of early joint effusions was quite noticeable. There was great difficulty in securing and maintaining the fragments in apposition, necessitating frequent changes in the method of treating individual cases. Fibrous union was the rule. This result is stated in eighty-four of the cases, and but four or five admitted of no movement of the fragments upon each other. Re-fracture, or rather giving way of the bond of union, occurred in twenty-seven cases. Anchylosis existed for a longer or shorter period, but disappeared within a year or two after the injury. Knee-caps, as a rule, served no good purpose while the patients walked about. And lastly, our author calls attention to the remarkable power of restoration of the functions of the limb, after a time, if only the patient continues to use the limb, and thus develop the muscles.

The work is well published, and presents a very attractive appearance.

◆

THE PATHOLOGY OF HYDROPHOBIA.—At a meeting of the Philadelphia County Medical Society in June, Dr. Chas. K. Mills read a paper on hydrophobia, and gave some rather heterodox opinions as to its pathology. He denied (1st) that hydrophobia is due to a special morbid virus; (2d) that it is accompanied by specific changes in the blood; or (3d) that it has any absolutely characteristic lesions in the central nervous system. He regarded the origin of the chief symptoms in most cases as capable of being explained on the view of peripheral nerve-irritation set up originally in the wound, and transferred by reflex action to the medulla oblongata. Many cases called hydrophobic are also, he believes, examples of recognizable and demonstrable disease of an entirely different character. Some cases result from fear or imagination. Hydrophobia is a kind of tetanus.—*Philadelphia Med. Times.*

SANITARY CONDITION OF PRINCETON.—The Sanitary Committee appointed by the trustees of Princeton College to examine into the cause of the late sickness have reported that the sickness was due to bad drainage, but that this is now remedied, and the college is now in good sanitary condition.

Reports of Societies.

THE NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 11, 1880.

DR. H. B. SANDS, PRESIDENT, IN THE CHAIR.

LIPOMA OF THE BACK—ABSORBABLE DRAINAGE-TUBE.

DR. FRED LANGE presented a patient, a middle-aged man, upon whom, three months ago, he operated for the removal of a moderate-sized lipoma situated in the scapular region, and applied a large antiseptic dressing, after having introduced Dr. Neuber's absorbable drainage-tube. The tube, however, had not been absorbed, but had been healed in, and the patient carried it about without inconvenience. The wound healed almost entirely by first intention. The small portion of the tube which was left protruding was separated from the portion that remained in the wound by absorption, and, as Dr. Lange believed, by the action of the granulations which rose from the edges of the wound at that place. He thought the reason why the remaining portion of the tube was not absorbed was because the patient, on the second day, made sufficient exertion to cause hemorrhage; and although not sufficient to necessitate removal of the dressing, when, a week afterward, the dressing was removed, it was noticeable that a small effusion of blood had occurred under the flaps. Neuber had reported cases in which absorption of the drainage-tube made of decalcified bone had been prevented by hemorrhage into the wound, and Dr. Lange thought that his case belonged to the same class. The blood does not act upon the tube in the same way as do the granulations. It seemed that the tube would gradually diminish in size, and after a time disappear entirely.

FRACTURE OF THE METACARPAL BONE OF THE THUMB —RESECTION.

Dr. Lange also presented a patient who, three months ago, was injured by a heavy piece of wood falling upon his right wrist. Fracture of the metacarpal bone of the thumb, near the carpo-metacarpal joint, was diagnosticated, and the case was treated accordingly; but there remained the pain and feeling of crepitation with every movement of the thumb, and the patient was unable to work. Dr. Lange then saw the case in consultation, thought that the fracture, perhaps, had extended into the joint, and proposed to open the joint and excise a portion of the bone if necessary. He found a small piece of bone that had been separated, and then united in an unfavorable position, so much so that a prominent ridge remained, bound by sharp edges, which continuously irritated the articular cartilage, and when removed it was found that the fracture had involved the articular surface, separating it into two parts. The wound made by the operation healed kindly, and the result was very good. The movements of the thumb were very good, and the patient suffered no pain except when direct pressure was made upon the parts. The operation was performed one month after the receipt of the injury.

DR. BRIDDON referred to a case in which he removed the entire metacarpal bone of the thumb on account of disease of the bone. The patient was a sailmaker, and recovered with the ability to handle his needle nearly unimpaired. Considerable new bone was formed.

Dr. A. C. Post then introduced the subject for the evening, namely:

CYSTOTOMY AND THE APPLICATION OF THE ACTUAL CAUTERY IN THE TREATMENT OF CYSTITIS.*

Dr. Briddon remarked that he had used the deep cautery in several cases of cystitis where either the obstruction had been removed or none existed, and with excellent effect. He had also used the superficial cautery in more moderate cases, and with moderately good effect. He had also seen cases which had not been benefited by the use of the actual cautery.

Dr. E. L. Keyes remarked that he had performed lateral cystotomy, in connection with Dr. Van Buren, for the relief of chronic cystitis in three cases. All of the patients had obtained a certain amount of relief, but he ascribed the relief in two of the cases not so much to the cystotomy as to the removal of median prostatic and outstanding overgrowths which formed an important feature of the operations. In the other case no relief was obtained except so long as the wound was kept open. One patient was a man, fifty-six years old, who had not passed his water without the aid of a catheter for four years. Phosphatic concretions were detected in the bladder at the end of this period, due to neglect of cleanliness of the bladder, and that was made the excuse for cutting, the main object being to relieve the patient of his median prostatic hypertrophy, which was readily recognized.

Phosphatic matter to the amount of a drachm and a half was removed, and a prominent third lobe twisted off and taken away. From that time the patient passed his water without a catheter; but he never ceased to have cystitis. Several years later he died from kidney complication.

In one case a pedunculated growth, which had acted as a ball-valve, suddenly arresting urination entirely, was twisted off during the operation of cystotomy, and the patient was very much relieved. He was in a moribund condition practically when the operation was performed, but is now living and quite comfortable. This patient would not use a catheter, because it hurt him, but injected his bladder through the urethra, by means of a fountain-syringe, with the greatest facility; yet there was about an ounce of residual urine, and therefore he did not get the full benefit of the washing. His chief relief came from the removal of the pedunculated growth.

A third case occurred in the person of a man æt. nineteen, who had a large kidney consisting largely of concentric layers of inspissated pus. The patient had red cheeks, was very fleshy, and apparently in full health. The bladder symptoms were reflex. This was a case of pure lateral cystotomy, nothing else being done, and the patient did very well for a while, the wound being kept open for about a month. As soon as the wound healed the old symptoms returned, and in about one year the patient died. The kidney was found as described. The bladder symptoms were unrelieved at the time of death.

Dr. Keyes remarked that he was familiar with three other cases, and in none of them was permanent relief obtained by lateral cystotomy. None of the patients died as an immediate result of the operation.

In the case in which the patient had the large kidney the wound was kept open with the finger for some time. In the other cases the wound was allowed to close promptly, and a certain amount of benefit followed the operation, because a pre-existing obstacle to urination had been removed. It seemed to him that the value of lateral cystotomy in cases of chronic cystitis was in proportion to the amount of rest given to the bladder at that time; but, if there be any cause for a continuance of vesical irritability, lateral cystotomy, as a directly curative procedure, was not valuable, excepting in so far as the element of rest was concerned.

Dr. Post asked Dr. Keyes if he practised divulsion after making the incision, and Dr. Keyes answered in the negative. Dr. Post then remarked that he attributed considerable importance to that step in his operation; because, as he stretched the parts, there was at once a considerably copious discharge of pus.

Dr. Erskine Mason referred to three cases of cystotomy in which he performed the operation for the relief of chronic cystitis as a *dernier ressort*. The first patient was fifty-six years of age, and had had urinary disease for twenty years; had a stricture that had been operated upon several times. The median portion of the prostate was enlarged and was removed, and the patient was greatly relieved by the operation. He died two months afterward, and post-mortem revealed cystic degeneration of the kidneys.

In the second case the patient was fifty-four years old, and died from uræmia.

The third patient was a mulatto, forty-nine years of age, who had quite a copious hemorrhage into the bladder three days after the operation. He died a few days afterward, from apparent uræmia, and at autopsy kidney disease was found.

Dr. Post remarked that there was one point in the history of his case which he omitted to mention, namely, that the patient for some time prior to the operation had been bedridden, but his recovery was so complete that by climbing over the wall he escaped from the hospital with out paying for his board, thus showing that he had attained a considerable degree of activity.

Dr. C. K. Briddon remarked that he had performed the operation twice, and both patients died shortly afterward while in coma, probably uræmic in character. He regarded divulsion as a bad feature in the operation. He thought that divulsing the neck of the bladder or prostatic portion of the urethra, in a patient with chronic cystitis, was likely to produce mischief.

Dr. Post remarked that the condition of his patient was improved immediately after the operation.

Dr. Post referred to a case in which he performed lithotomy on a patient who had pyelitis. Recovery from the lithotomy took place, and the patient was considerably relieved by the operation; but for a long time his urine contained pus that doubtless came from the pelvis of the kidney.

Dr. Robert F. Weir remarked that he had had occasion to study the literature of the subject recently, and had gathered nineteen cases, which, with the ten new cases just mentioned, made a total of twenty-nine, with eleven deaths, thus showing that the mortality is quite large. In some of the cases a departure from the lateral operation was made.

The first case was reported by Sir William Fergusson in 1850, who did the simple median operation, making the cut, as the report reads, so as to "divide the plexuses of nerves connected with the prostate," in order to relieve the man from the spasmodic condition.

---

* This case has been published in a previous number of the Medical Record.

That was followed in order of time by Dr. Willard Parker's case, operated 1855, which was reported in a paper read before the Medical Society of the State of New York, in February, 1867.

In June of the same year McCraith, of Syria, did the median operation and then made a section of the prostate to a slight extent.

In October of the same year, Bickersteth, of Liverpool, published a paper in which he stated that for about ten years he had resorted to the lateral operation for the cure of cystitis, and that it had, as a rule, relieved his patients. His line of reasoning was similar to that presented by Dr. Parker.

Eve subsequently did the bilateral operation, and Teevan quite recently resorted to the median operation with success.

Bryant had reported six cases, with three deaths, and made the statement that when kidney trouble was recognized the operation should not be undertaken.

Howe had done one operation, opening the perineum in the median line, introducing the finger and dilating without cutting, with a successful result.

In Powell's case, which has been quoted by Gross, lateral section of the prostate was made, singularly, for extravasation of urine into the scrotum and perineum.

Little had done the operation several times, and the point to which he directed special attention was the difficulty in keeping the opening in the prostate patent.

Dr. Keyes asked if there was any case upon record in which lateral cystotomy, independent of any other means, had effected a cure?

Dr. Weir replied that McCraith spoke of his case as one of perfect recovery. It was not, however, one of pure lateral cystotomy. Bickersteth's was, and the cure was permanent. Several others existed, but in a large number the result was either negative or only a partial improvement.

Dr. Keyes remarked that, as a rational means of cure, there was no special reason why it should succeed unless aided by other measures.

Dr. Weir remarked that in the younger subject the operation seemed to afford more relief than in the older subject when the prostatic element existed. In cases in which a portion of the prostate has been removed the benefit has been most marked.

Dr. Post remarked that he had performed the operation once in a female, and all signs of inflammation disappeared. The fistula remained open for a long time.

Dr. Weir remarked that section and removal of the median portion of the prostate, first alluded to by Fergusson, had been performed several times by Bryant, who rather encouraged the intentional removal of this portion.

Dr. Mason remarked that Guthrie suggested the removal of the median portion many years ago. Mercier cut through it, and Guthrie removed it.

Dr. T. M. Markoe remarked that it seemed to him the median operation was not in any wise suitable for the purpose of giving the bladder rest, for one of the advantages claimed for it was that it did not prevent closure of the sphincter, and therefore could not give rest. He thought he should always prefer the lateral operation.

The President remarked that the median operation had been done with the insertion of a tube, for the purpose of securing rest.

Dr. Markoe remarked that the tube might partially accomplish it temporarily.

GANGRENE OF THE FOOT AND LEG.

Dr. C. K. Briddon referred to the case which he reported at the last stated meeting. (See Minutes for April 27, 1880.) He performed amputation at the knee-joint, making anterior and posterior flaps of the same length. The popliteal artery was pervious; the branches given off from it were markedly atheromatous. Gangrene followed, and destroyed about two inches of the anterior flap, the posterior flap remaining intact. Had he not made the posterior flap equal in length with the anterior, there would have been a scarcity of tissue; but, as it was, he thought there would be sufficient to make a good covering for the stump.

ACUTE PROSTATITIS FOLLOWING THE INTRODUCTION OF A SOUND.

The President reported a case which illustrated the liability to serious consequences from what are usually perfectly innocent operations upon the urinary apparatus.

Two years ago he was called in consultation to see a patient, about thirty-three years of age, who was suffering from inflammation of the right testicle. The inflammation was severe, and had occurred very suddenly after the introduction of a large-sized steel sound into the bladder. It was supposed that the patient was suffering from the consequences of ungratified sexual desire. He had no venereal disease, but was melancholic, and experienced various uneasy sensations in the deeper portion of the urethra.

The physician with whom Dr. Sands saw the case had been treating the patient by galvanization of the prostatic urethra. The accident did not immediately follow an application of electricity, but followed the introduction of a sound, not by the physician himself, but by the patient, who had acquired great skill in the use of the instrument. The attack was very severe. There was high fever, at one time delirium, some typhoid symptoms, as dry tongue, etc., and at the end of a week or ten days there was fluctuation beneath the skin of the scrotum, which was opened and vent given to the pus, and to Dr. Sands' surprise and disappointment the secreting tubes of the testicle protruded from the opening. Despite all efforts to the contrary, all the testicular substance escaped, and the tunica albuginea alone remained. The patient recovered his health, and eight months ago was married. He was quite well at the time of his marriage, and remained so during two of the three months spent on his wedding trip in Europe. Two months after his marriage his wife became ill with uterine trouble of such a nature as to forbid sexual intercourse, and with that enforced abstinence the husband's old troubles reappeared, the uneasy sensations in the deep urethra, etc. He was then treated by an eminent surgeon in Philadelphia for a so-called stricture of large calibre. The stricture was divided, with some relief, but this was only temporary. He returned to New York and placed himself under the care of a competent surgeon, with whom Dr. Sands saw him, and that surgeon treated him again with sounds. At that time there was no urethritis, no cystitis; indeed the symptoms were quite subjective. After the introduction of a large-sized sound the patient was seized with severe fever, had great desire to micturate, his urine was purulent, and he had all the signs of acute prostatitis, evidenced not only by the symptoms mentioned, but by a tumor readily felt in the rectum.

Dr. Sands saw him about two weeks ago, and at the time of the first visit he was able to detect an enlarged prostate, which was tender, and he suspected that it was about to undergo suppuration, if this had not already occurred. This view of the case was confirmed by the appearance, at intervals of two or three days, of large quantities of pus in the urine, forming a sediment, in an eight-ounce vial, about an inch in depth, and presenting very much the appearance of pus in the urine in cases of pyelitis.

Three days after his first visit, Dr. Sands saw the patient again, when there was a large swelling in the right buttock, similar in appearance to an ischiorectal abscess. It was deeply seated, covered an area about four inches in diameter, and could be felt through the rectum. It did not suppurate, but in the course of four or five days eleven additional deep-seated phlegmonous swellings appeared, and with the exception of this one all were situated upon the extremities; the first in the right calf, the second in the left calf, and others of lesser size in other localities. None of the swellings suppurated. But the most recent and the most interesting development was the appearance of a swelling, of the size and shape of a hen's egg, in the right side of the perineum, and occupying the scrotum to about one-half its extent. The swelling looked not unlike a hernia, and examination was made with a view to differential diagnosis upon that point. Dr. Sands saw this swelling for the first time May 10th, and was able to appreciate an indistinct sense of fluctuation. The attending surgeon introduced a hypodermic syringe and obtained pus. It was then proposed to open the swelling, and as Dr. Sands was endeavoring by pressure to make it tense and prominent, it became softer, and presently receded altogether, with the exception of a small, hard mass, about half as large as the last joint of the thumb, felt deep in the perineum and behind the spermatic cord. This disappearance of the swelling under pressure made both himself and the attending surgeon suspect that the abscess communicated with the bladder, into which its contents had probably escaped. The patient was accordingly directed to pass his urine, when it was observed that about a tablespoonful of clear water flowed first, and then about two ounces of clear pus, containing a small and recent blood-clot. That fact made it almost certain that the abscess had some connection with the bladder.

The case was interesting as showing how severe an accident might sometimes follow a simple surgical procedure, and interesting also anatomically with reference to the route by which the abscess had extended from the pelvic cavity to the perineum. Evidently the matter had not followed the course of the urethra, but had either ruptured, or more probably passed below the triangular ligament. He also asked what would be the effect of opening the swelling in the perineum if it communicates with the bladder. Could the urine escape and a urinary fistula be established, at least temporarily? All acute symptoms had subsided, and nothing was discovered through the rectum except a moderately enlarged prostate. There was always pus in the urine, but it was copious only about every second or third day.

Dr. Post remarked that it was an old surgical rule to give external discharge to collections of pus when it could be done. In this case he thought the occurrence of a fistula would be a minor evil as compared with results that might occur without drainage being effected.

Dr. Keyes remarked that he could not see why the abscess should not be opened, in order to prevent further complication. With an extensive external incision there was no reason why the internal orifice of the fistula might not close, and if it did not close readily the internal orifice might be found through the wound and the whole fistula, perhaps, freely opened into the bladder.

Dr. Weir remarked that if the pus could get into the bladder or urethra, the urine could also get into the cavity of the abscess, and hence the external opening would be inoperative.

He had seen a prostatic abscess discharge in the perineum, but had never noticed any such symptom as disappearance of the swelling under pressure, and in his case there was also wanting any marked swelling in the rectal examination.

He thought that the complication of swellings appearing at various points upon the body was only a milder form of the urinary complication described by Velpeau, and sometimes seen after the slighter as well as the severer operations.

Sometimes the swellings go on to suppuration.

It could be called a septicæmic process, although not always a fatal one.

Dr. Mason recalled a case of acute prostatitis following gonorrhœa, when a tumor made its appearance in the perineum. The prostate was much swollen and very tender, and the patient had a good deal of difficulty in urinating. The swelling was opened, and the wound closed without difficulty.

Dr. Weir was of the opinion that these fascial layers were not always so strong as commonly found to be on dissection, inasmuch as false passages, starting anterior to a stricture, would sometimes be followed by abscess posterior to the deep layer of the triangular ligament; and also that recently he had seen abscesses in the region set up by instrumental violence to the prostatic urethra opened well forward in the scrotum. In other words, dissection and experience proved that the resistance of these layers of fascia varied much in different individuals.

◆

A New Veterinary Journal.—*The Veterinary Gazette*, a monthly journal of practical veterinary medicine and surgery, has recently been sent to us. It is edited by Chas. A. Meyer, D.V.S., Jas. Hamill, D.V.S., and H. E. Earl, D.V.S. It is somewhat difficult to tell whether its appearance indicates veterinary progress so much as personal feeling. It professes to be independent, but aims its guns pretty regularly every month at the Columbia Veterinary College. This may be all right, however, and we venture no opinion, except that it does not appear independent, or in good taste, for a person who has just resigned his office to devote the immediate succeeding months to "pitching into" his former colleagues. The *Gazette* is well made up and contains much interesting matter aside from its polemics.

The Discovery of the Pulmonary Circulation.—M. Achille Chéreau read a paper before the Academy of Medicine in Paris, in which he showed that the true discoverer of the pulmonary circulation was not Michel Servetus, as is commonly supposed, but Colombo, of Cremona. Servetus published his book, in which he describes the pulmonary circulation, two years before Colombo's work appeared. But it is shown that Colombo had taught the pulmonary circulation for many years before the publication of his book. And Servetus was one of his pupils.

Correspondence.

ON THE RELATIONS OF NERVE AND MUSCLE.

To the Editor of The Medical Record.

Sir :—I think it no more than justice to myself that I should say a few words in answer to Dr. Poole, as he appeared in a letter entitled "A Reply," in the Record of August 7th. I am accused of not being to the point in my letter published on this subject. Of course I have no further acquaintance with the explanation which he advocates of the physiology of muscular action than I can get from reading his papers; and after reading his reply, I am obliged to say that his theory, which I had thought I comprehended, is now in my mind somewhat uncertain.

I am first taken to task in these words: "This omission shows how little pains he has taken to grasp the subject as I have presented it." In defence I must say that at the time of my writing, his explanation of the non-instantaneous muscular contraction after death had not yet appeared.

Your correspondent says: "I have never asserted or implied that relaxation is active and contraction passive." While I regret exceedingly having thus mistaken his meaning, I cannot yet see any particular stupidity in my thus understanding him. In the Record of May 1st he says: "Why should it be taken for granted that the ordinary or extraordinary exercise of muscular contractile power is dependent on a *stimulus* from the nervous system? . . . It will not do to accept such an opinion because the response of the muscle to the will seems to justify it." Now it is perfectly reasonable to suppose that if the muscles do not contract under the nerve-action, they must certainly relax. There must be nerve-action, else why the nervous system. In the very expression "nerve-action" there is an active condition indicated, and if this is not contraction, as is ordinarily thought, it must be relaxation, which would then be active. Again, a stimulus is "anything which excites the animal economy" (Dunglison), or, in other words, anything which produces action. If, then, contraction is not produced by a stimulus, it must be passive. Dr. Poole emphasizes the word "stimulus." This precludes for it any other source than the nervous system, and if contraction does not depend on a stimulus, it must depend on the only other possible thing, the withdrawal of a stimulus.

The information that "ligaturing a nerve-trunk arrests its power of conducting nerve-force" is not at all surprising; neither is it that the pressure of an intracranial tumor, or the rupture of a blood-vessel, will result in paralysis. I am informed also that "the cramps in the limbs of a parturient woman, knotting the muscles, are due to the arrest of nerve-force." The clear perception of the meaning of the term "paralysis" previously entertained, now becomes clouded. Before, the idea associated with it was complete muscular relaxation, the limb hanging helplessly, or, in case of a single group of muscles, distortion through the contraction of the opposing set which are no longer restrained.

But this is not the condition of things in the case of pressure by the fœtus. On the contrary, the muscles are painfully contracted. Are these two opposite conditions both to be considered paralysis? If we believe that there is an arrest of nerve-force, we must admit that they both are; then also we must consider tetanus, which has the same symptoms, to be paralysis. Yet how different from that resulting from compression of the brain, or the pressure of adventitious growths. Is it not at least reasonable to suppose that the ligation of a nerve-trunk, which results in paralysis, causes actual injury? Will the power of motion return on the removal of the ligature, or will the parts supplied remain helpless until the integrity of the nerve is restored, and above all, are the muscles painfully contracted?

The idea of spasms and convulsions (incorrectly, conditions) being caused by anything else than nerve-activity is ridiculed. If this is not the case, as good an authority as Erichsen has been deluded, since he says: "Tetanus is especially apt to occur in the feeble and debilitated, and indeed may be looked upon as a disease of debility, since any condition that lowers the tone of the nervous system is especially liable to occasion it" (page 575).

Dr. Poole speaks of me as being "unable to prove that in functional disturbances of a paralytic kind, or that amid atrophy, degeneration, and disintegration of nerve-tissue, there is a possibility of increased nerve-action." First, can he prove that this horrible state of things does ever exist, except in the imagination? The bare possibility of this might be suggested by Bryant ("Prac. of Surg," p. 185) in speaking of the pathology of tetanus. After speaking of structural changes which Dr. Poole asserts as existing, and which some have claimed to have found, he says: "Yet it is to be remembered that Billroth and other pathologists have failed to find these changes in the instances they have examined." In regard to the pathology of convulsions, Aitkin ("Sc. and Prac. of Med.," vol. ii., p. 316) says: "No characteristic or constant change can be detected in the nervous centres after death." The etiology of this abnormal condition is so diverse, that to ascribe to it a pathological histology would be as gratuitous as to endeavor to detect an encephalic lesion for pain. Attributable as it is to injuries of the head, to organic diseases of the brain and cord, to vascular disturbances of the brain, to the circulation of abnormal blood, to reflex irritation, as intestinal worms, digestive disorders, or even the prick of a pin, it must, with pyrexia and rigor, be regarded only as a symptom.

In view of the fact that spasms and convulsions are also treated with narcotics and sedatives quite as satisfactorily as with stimulants, I can imagine Dr. Poole being in the same predicament as he ascribes to me. Indeed, Bryant says that "stimulants must be used cautiously."

When I wrote my first letter, termed by Dr. Poole a "criticism" (though I did not intend it as such), I mistook his theory. If he supports the hypotheses of DuBois-Raymond, as set forth by Radcliffe, as I imagine he does, no discussion is necessary. They have not been accepted by the greatest physiologists, and the existence of "muscular currents" other than artificial, if not disproved, is rendered extremely doubtful. A very interesting consideration of this subject may be found in Foster's "Text-Book of Physiology," page 62 *et seq.* My sole object in writing this is to deny the accusation of superficiality which has been made, and place myself in the proper light before those who have taken any interest in the subject.

Respectfully,
W. C. McGiffert, A.B.

Hudson, N. Y., Aug. 12, 1880.

WHAT IS "MEDDLESOME MIDWIFERY?"

To the Editor of The Medical Record.

SIR:—It was Ramsbotham, I think, who first made use of the expression, "meddlesome midwifery is bad." He, no doubt, used it for the purpose of condemning any officious interference with natural labor. Normal labor is a physiological act, and nature, unassisted, is usually able to accomplish her purpose. The accoucheur has no more business to interfere with the uterus when it is discharging its function, than he has to interfere with the bladder or rectum when they are discharging their functions. It is his business—and his only business—when the labor is natural, to preserve a "masterly inactivity." To do anything under these circumstances, is to be meddlesome; and it was for the purpose of condemning the everlasting interference with nature, which is so common with some practitioners, that the distinguished author made use of the expression, "meddlesome midwifery is bad." It is clear, terse, and forcible, and has come to be a proverb in medical parlance. But, notwithstanding it is so plain, there are physicians who are so stupid as to have completely failed to understand its meaning. The flippant manner in which the phrase is misapplied, and in which it is dragged in on all possible occasions, has rendered it trite and unmeaning. At the meetings of our medical societies, no member can suggest any improvement in the obstetric art, but some one will rise and, with an expression that is childlike and bland, say, "Yes, that may be all very well, but you know that that distinguished practitioner and author, Mr. Ramsbotham has said 'meddlesome midwifery is bad.'" He will then sit down happy in the thought that he has utterly squelched the brother who had the temerity to intimate that under any circumstances nature could receive assistance from art. Not many years ago, I remember hearing a paper read at a county medical society by a young physician on the use of the obstetrical forceps. It was an excellent paper. In it the author dwelt upon the relief from suffering which its use was capable of giving to the parturient woman.

When he had finished, an old gentleman from the rural districts arose and in a very dignified and impressive manner stated that he had been practicing midwifery over thirty years; that he had delivered over three thousand women, and that he stated (as if it was something to be proud of) that he had never used the obstetrical forceps He did not tell how many of his patients had died undelivered, nor how often he had used the perforator, nor how many had suffered from vesico-vaginal fistula, nor how much unnecessary suffering both he and his patients had endured, which might have been saved by a judicious use of the forceps, but he did not fail to mention, before sitting down, that "an old and distinguished practitioner had said that 'meddlesome midwifery is bad.'" As he said this he fastened his eagle eye upon the young man who had read the paper, and the young man looked as if he had been sat down upon.

A few evenings since I had the honor to report to the Alleghany County Medical Society the history of a case of abortion at the fourth month. In this case there was profuse hemorrhage, and the placenta was retained. I, with a good deal of difficulty, succeeded in removing the placenta in the manner recommended by Dr. W. T. Lusk, of New York, when the hemorrhage was arrested and the case went on to a favorable issue.

I dwelt upon the importance of making persistent efforts to deliver the placenta in such cases. When I had finished I was not surprised when one of the members arose and in a cheerful, smiling manner, as if an original idea had just struck him, crushed me with this remark: "I do not approve of the practice, for you know 'meddlesome midwifery is bad.'"

This sentence seems to be as far as many ever get in the obstetrical art, and even this is not understood by them. I have observed that those who are most apt to condemn interference when it is really necessary are the very ones who are most officious in trivial matters. To meddle is to annoy, but it is never meddlesome to assist.

In a case of natural labor, it is meddlesome to require a woman to assume any position which is repulsive to her. It is meddlesome to introduce the finger into the rectum and endeavor to pull down the head. It is meddlesome to press upon the perineum and pull it either forward or backward. It is meddlesome to trouble a young girl having her first baby, by telling her when she should hold her breath and when she should bear down, and it is meddlesome to do many other things which are customary but are not only useless but annoying.

But it is not meddlesome to assist nature when she is unable to do her own work, nor is it meddlesome to set her right when she is wrong. Nor is it meddlesome midwifery to put a speedy end to a tedious case of labor with the forceps, nor to deliver with the hand a retained placenta in case of hemorrhage.

I hope I may be pardoned for dwelling so long upon this subject, but I have heard the expression "meddlesome midwifery is bad," so often misapplied, that I am heartily sick of it.

J. B. Murdoch, M.D.

Pittsburg, Pa., July 16, 1880.

SANITARY ADMINISTRATION AND EPIDEMIC DISEASE.

To the Editor of The Medical Record.

SIR:—It gives me great pleasure to remark the fact that my excellent friend, Dr. Reyburn, has done me the honor to read and to consider my recent paper on the above entitled subject. The good doctor seems to think that I am "hardly fair to sanitarians, for the great and ultimate object of all sanitary science is this very prevention and removal of the causes of disease." Precisely so. But when so-called sanitarians, through ignorance of the first principles of their science. undertake to combat disease with methods which will inevitably increase the aggregate of disease and suffering in the world, they need instruction.

As for the statement that disease being "a result of a want of proper correspondence between the habits and mode of life of the individual and his environment; hence it is not in consonance with the normal law of nature, but antagonistic to it," I must say that this does not correspond with my observation of the process of nature. When the habits and mode of life of an individual do not conform to the necessities of his environment, either the environment or the habits of the individual must be modified, or there will be perpetual conflict and discomfort, which may even rise to the altitude of disease. To a certain extent man has the power of modifying his environment, but the majority of physical forces will not yield to the will of man. He must either conform to them, or succumb to them. When this process of adaptation is hastily conducted, it usually produces a series of phenomena which we call disease—as when a child is brought in conflict with the poison of scarlet fever in his environment. The way of wisdom leads us to search out the nature of such hostile forces, and to either remove them or to learn how to adjust ourselves to their presence if they cannot be obviated. We have made considerable progress with certain of these forces, but many of them still elude our grasp. What we need to know more about is the *modus vivendi* in connection with diseases whose causes escape our control. Such a disease was small-pox, a disease which we have robbed of its terrors by domestication—by subjecting ourselves to its continual action and presence in the community. I am very well aware that this view of the subject appears novel to those who are not acquainted with the nature of the relations between variola and vaccinia, but it would not be generous to reproach any one for such lack of information, for it is only a few months since no less a person than Sir Thomas Watson was compelled to confess his life-long ignorance regarding this very matter. Dr. Reyburn's statement that by the passage of small-pox virus through the cow "a new disease is produced," is wholly at variance with the doctrines of natural science—is, in fact, a statement that no one could make who has reflected upon the subject of specific differences. Some time, when leisure returns to me, I shall endeavor to elucidate this interesting subject.

My friend asks if I "mean to say that the mortality from these diseases (scarlet fever, measles, etc.) was diminished by their spread in the community?" That is precisely the idea which observation impresses upon those who take a comprehensive survey of the subject. I cannot now take the time to illustrate the subject in any adequate manner. I will simply quote one example: When measles for the first time in the history of mankind invaded the Sandwich Islands, it destroyed one-tenth of the entire population. The people possessed no hereditary tolerance as a protection against the ravages of the disease and its sequelæ. The value of such protection was shown by the fact that during the same epidemic the children of American and European residents suffered no greater degree of mortality than is experienced during the regularly recurring epidemics of measles in our own country. Since that date the adjustment of the remnant of that population to measles has become so complete that now it occasions very little more than the average American mortality when it prevails in the Pacific.

I have no doubt that if our enthusiasts could succeed in stamping out measles and scarlet fever in our country for a few generations, our descendants would some day be more than decimated by an unexpected epidemic. Five million deaths from measles in these United States during the space of six months is what might now occur at any time if our population were not protected by that hereditary tolerance of the disease which grows out of its almost constant prevalence in the community. It is better to keep such an enemy in a state of domestication, rather than to banish him to the wilderness whence he may sally forth at any moment with overwhelming violence to ravage our households.

As for the remark that history shows, "by irrefragable proofs, that the vigor and length of life in modern times has increased, whilst many of the epidemic diseases, such as the plague, typhus fever, small-pox, etc., have almost disappeared from the world's history," it is difficult to refrain from a feeling of surprise that any one could fail to notice the bearing of natural selection upon these results so far as they are real. It is the long-continued weeding of our communities by disease that has contributed so largely to bring the human race to its present condition. A stern and unremitting process of natural selection, permitting only the survival of the fittest, is one of the principal causes of national vigor. Just as soon as this process is interfered with by the misguided efforts of ignorant man, deterioration of the species begins. In this connection it is suspiciously significant that during the past forty years of sanitary enthusiasm in England, the average duration of life in that country has not increased. Sanitarians, when confronted with this uncomplimentary fact, attempt to parry its force by asserting that if it had not been for them the standard duration would have been diminished instead of remaining stationary. For this claim there is no logical basis. Could they show that the duration of life had been steadily diminishing until the commencement of the last forty years' period, there might be some show of reason in their claim. But as I have not time now to discuss the value of natural selection as a means of elevating the human race, let me commend to the consideration of my friends the following eloquent passages from the writings of Herbert Spencer—a teacher whom the busybodies of our day would do well to consult before they undertake the work of giving advice regarding the management of the universe.

"Pervading all nature we may see at work a stern discipline, which is a little cruel that it may be very kind. . . . The development of the higher creation is a progress toward a form of being capable of a happiness undiminished by these drawbacks. It is in the human race that the consummation is to be accomplished. Civilization is the last stage of its accomplishment. And the ideal man is the man in whom all the conditions of that accomplishment are fulfilled. Meanwhile the well-being of existing humanity, and the unfolding of it into this ultimate perfection, are both secured by that same beneficent, though severe discipline, to which the animate creation at large is subject: a discipline which is pitiless in the working out of good: a felicity-pursuing law which never swerves for the avoidance of partial and temporary suffering. . . . It seems hard that an unskilfulness which, with all his efforts, he cannot overcome, should entail hunger upon the artisan. It seems hard that widows and orphans should be left to struggle for life or death. Nevertheless, when regarded not separately, but in connection with the interests of universal humanity, these harsh fatalities are seen to be full of the highest beneficence—the same beneficence which brings to early graves the children of diseased parents, and singles out the low-spirited, the intemperate, and the debilitated as the victims of an epidemic.

"There are many very amiable people—people over whom, in so far as their feelings are concerned, we may fitly rejoice—who have not the nerve to look this matter fairly in the face. Disabled as they are by their sympathies with present suffering, from duly regarding ultimate consequences, they pursue a course which is very injudicious, and in the end even cruel. . . . We must call those spurious philanthropists who, to prevent present misery, would entail greater misery upon future generations. . . . A sad population of imbeciles would our schemers fill the world with, could their plans last. A sorry kind of human constitution would they make for us—a constitution lacking the power to uphold itself, and requiring to be kept alive by superintendence from without—a constitution continually going wrong, and needing to be set right again—a constitution ever tending to self-destruction. Why, the whole effort of nature is to get rid of such, to clear the world of them, and make room for better. Nature demands that every being shall be self-sufficing. All that are not so nature is perpetually withdrawing by death. Intelligence sufficient to avoid danger, power enough to fulfil every condition, ability to cope with the necessities of existence—these are qualifications invariably insisted on. Mark how the diseased are dealt with. Consumptive patients, with lungs incompetent to perform the duties of lungs, people with assimilative organs that will not take up enough nutriment, people with defective hearts that break down under excitement of the circulation, people with any constitutional flaw preventing the due fulfilment of the conditions of life, are continually dying out, and leaving behind those fit for the climate, food, and habits to which they are born. Even the less imperfectly organized, who, under ordinary circumstances, can manage to live with comfort, are still the first to be carried off by epidemics; and only such as are robust enough to resist these—that is, only such as are tolerably well adapted to both the usual and incidental necessities of existence—remain. And thus is the race kept free from vitiation."

How refreshingly the healthy vigor of these utterances contrasts itself with the sickly sentimentalism that is just now so fashionable in certain circles—even within the ranks of our own profession!

Henry M. Lyman.

Chicago.

Uterine Dyskinesia and the Treatment of Displacements.—Uterine dyskinesia is a new gynecological term, introduced by Dr. Graily Hewitt, and used to express the difficulty in walking that accompanies certain uterine diseases. In a report upon sixty-seven cases of uterine distortion or displacement coming under Dr. Hewitt's care, he noticed this symptom as occurring with remarkable frequency. Physical exertion induces a temporary exaggeration of the difficulty, hence exercise is given up and helpless invalidism is likely to ensue. Another point noticed in these cases, which, by the way, were of persons of the better class, was the frequent existence of starvation. Not enough food was taken, and the uterine tissues softened and lost their tonicity. In many cases, nausea was also a frequent symptom of the uterine displacement. This nausea sometimes led to the taking an insufficient quantity of food; the result was starvation; the starvation in these cases being secondary to the uterine disease.

The treatment employed was largely hygienic. In some starvation cases food was given every hour; sponge baths and friction to the skin were used. The postural method was largely followed. The patients were kept recumbent: in the dorsal position in the case of forward displacements; in the semiprone position in cases of backward displacements. In cases of forward displacement the cradle-pessary, in backward the Hodge pessary, was employed. The sound was used at intervals to aid in restoring the uterus to proper shape, when the organ was found hardened in its distorted shape. The treatment of the cases generally covered a long time, but eventually most of the patients were restored to health.

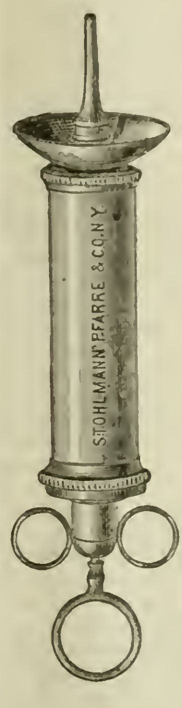
New Instruments.

A MODIFIED TIP AND PROTECTING FLANGE APPLIED TO THE EAR-SYRINGE.

By O. D. POMEROY, M.D.

The above modification has been constructed and used by me for a number of years with great satisfaction.

A few days since, in syringing an ear at the hospital, I found the tip of the syringe too short to reach far enough into the canal, besides being constructed with a swollen portion to prevent its going far enough into the ear to lacerate the membrane or canal. The aperture, also, was too large, preventing the production of a tense stream, the better to remove foreign substances from the ear. The return current also was inclined to spurt into the operator's face. I then used a syringe after the above model and succeeded at once in removing the obstruction.



The cut represents a syringe with a long slender nozzle, which may reach nearly or quite to the drum-membrane. The flange behind effectually catches any spurting of the return current, thus protecting the operator's face. The dimensions are as follows: length of the nozzle, five centimetres; diameter at the tip, two millimetres; at the opposite extremity, five millimetres; diameter of the perforation, one millimetre; diameter of the flange, five centimetres and three millimetres. Its concave surface presents toward the ear to be syringed. The whole is made of brass.

A good syringe should have the following advantages: 1. It should be worked with one hand. 2. It should have a nozzle long enough to reach the bottom of the drum-cavity. 3. Its aperture should be small enough to result in a stream of high tension, but with a good volume. The syringe represented is a brass syringe, suggested by the late Mr. Toynbee, and is of two ounces capacity. As this nozzle is so long and pointed it should not be put into the hands of the laity, for the drum-membrane could easily be punctured by unskilled manipulation. This instrument is made in the most admirable manner by Stohlman, Pfarre & Co., New York.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 22, 1880, *to August* 28, 1880.

White, C. B., Maj. and Surgeon. His sick leave of absence further extended three months on surgeon's certificate of disability, S. O. 181, A. G. O., August 25, 1880.

Ainsworth, F. C., Capt. and Asst. Surgeon. When relieved, to comply with S. O. 89, C. S., A. G. O., in his case. S. O. 100, Dept. of Arizona, August 10, 1880.

Skinner, J. O., Capt. and Asst. Surgeon. Assigned to duty at Whipple Barracks, A. T., relieving Asst. Surgeon Ainsworth. S. O. 100, C. S., Dept. of Arizona.

Comegys, E. T., Capt. and Asst. Surgeon. Granted leave of absence for four months. S. O. 181, C. S. A. G. O.

Powell, J. L., 1st Lieut. and Asst. Surgeon. Granted leave of absence for twenty days, permission to leave the Department, and apply for ten days' extension, provided he furnish an acceptable substitute, without expense to the U. S., during his absence. S. O. 157, Dept. of Texas, August 19, 1880.

Ebert, R. G., 1st Lieut. and Asst. Surgeon. Assigned to duty at Fort Walla Walla, W. T. S. O. 140, Dept. of the Columbia, August 16, 1880.

Habits and Treatment of Felidæ in Captivity. —Mr. Wm. A. Conklin, Director of the New York Central Park Zoölogical Gardens, writes a very interesting article on the above subject in the *Archives of Comparative Medicine and Surgery.* The food of the felidæ, he says, is either beef or horse-flesh. They are fed on week-days only, and fast on Sundays. The animals understand this perfectly, and on Sundays give no sign of expectation when the usual hour of feeding comes round. Occasionally some of the animals voluntarily abstain from food for as long as ten days, and do not appear to suffer. One of the difficulties to guard against is constipation. To prevent this, liver is fed to the animals once a week; when this proves ineffectual, castor oil is administered with their meat. All the felidæ are very fond of catnip, and, when it is placed in the cage, enjoy rolling in it.

The felidæ live in captivity from fifteen to sixteen years, showing signs of decay at about the age of twelve. The lion seems to breed more freely than any other species. The male will serve the female at least thirty times a day, as long as she is in season, which lasts generally ten or twelve days. The jaguar and leopard have been crossed, as also the tiger and lion. The period of gestation in the lion, tiger, and hyena is sixteen weeks; the number at birth is usually from two to four.

The cubs at the New York menagerie suffer chiefly from rickets, which affects them when about six or eight months old. As a remedy for this, phosphate of lime is used, with good results. In some cases cleft palate appears. The lions may be very prolific. In one case, a lion at the Dublin Zoölogical Gardens gave birth to fifty-four cubs, fifty of which she succeeded in raising.

An Arithmetical Phenomenon.—One of the last things done by the late Dr. Paul Broca was to present a most curious human specimen to the Anthropological Society of Paris. This was a lad aged eleven, a Piedmontese, named Jacques Duandi. He left his native place a short time ago, and, in company with a monkey, earned his livelihood by begging. When his appeals in the ordinary way were not attended to, he offered to solve mentally, in a few minutes, and without assistance of any kind, the most difficult problems in arithmetic. He was often put to the test; and, during his sojourn at Marseilles, a gentleman to whom he had appealed for charity was so astonished with the lad's gift of calculation, that he was induced to bring him to Paris as a curiosity. When M. Broca presented him to the Society, he gave him verbally a sum in multiplication composed of some trillions to be multiplied by billions. This he accomplished in less than ten minutes, mentally, and without any aid whatever, in the presence of the members, who were struck with astonishment. The lad is far from intelligent in other respects, and can neither read nor write. The most curious feature of his calculation is that he proceeds from left to right instead of from right to left. He is of the ordinary stature of his age, but his head is rather large and somewhat hydrocephalous in appearance. His forehead is high and developed to an extraordinary degree.

The case suggests that of an imbecile in a Pennsylvania asylum, recently reported, who had a most remarkable memory; without previous cultivation it was phenomenally greater than that of most men; while the other mental faculties were slightly developed. The talent for music and mimicry possessed by "Blind Tom" are, as is well known, associated with a very low order of intelligence. A collection and study of cases of this kind, which are not so extremely rare, would be of much interest to psychology.

Yellow Fever in Havana.—During the month of July there were 282 deaths from yellow fever in Havana. The total number of deaths was 1,017 in a population of 195,437.

A Supposed Case of Yellow Fever was discovered in Bellevue Hospital on the 14th ult. The patient was a man from Galveston who died two days after admission to the hospital, with symptoms pointing to yellow fever. The autopsy did not settle the question, but the wards were fumigated as though the case were a genuine one, and the death certificate read "collapse from supposed yellow fever."

Meetings of Scientific Associations.—The American Association for the Advancement of Science, held its annual meeting at Boston during the week beginning August 25th. The meeting was an unusually large one. A subsection on biology was established. Many papers were read before this and other sections, of much interest to physicians.

The British and the French Associations for the Advancement of Science were in session at the same time with the American. The British Association met at Swansea, the French at Rheims.

The British Medical Association finished its four days' meeting August 13th, and was, says the *British Medical Journal*, an unqualified success. Full reports of these meetings will be given later.

U. S. Marine Hospital Service.—Under the direction of the Treasury Department, Hon. John Sherman, Secretary of the Treasury; Surgeon-General, Dr. John B. Hamilton; Medical Purveyor, Oscar Oldberg, Ph.D.

TABLE OF PRINCIPAL STATIONS, ALPHABETICALLY ARRANGED.

Port.	Location of Hospital.	Name of Officer in Charge.
Baltimore	† City Hosp.	Asst. Surg. C. B. Goldsborough.
Boston	* Chelsea	Surgeon John Vansant.
Buffalo	† City Hosp.	Asst. Surgeon H. P. Cooke.
Cairo	† St. Mary's	Asst. Surgeon H. R. Carter.
Charleston	† City Hosp.	Asst. Surgeon F. Irwin.
Chicago	* Lake View	Surgeon T. W. Miller.
Cincinnati	†	Surgeon Walter Wyman.
Detroit	*	Surgeon W. H. Hutton.
Galveston	† St. Mary's	Pass. Asst. Surgeon H. Smith.
Georgetown, D. C.	† Providence	Pass. Asst. Surg. J. C. Fisher.
Key West	*	Asst. Surg. W. C. W. Glazier.
Louisville	*	Surgeon W. H. Long.
Mobile	*	Asst. Surgeon Godfrey.
New York	* Bedloe's Island	Surgeon C. S. D. Fessenden.
New Orleans	† Hôtel Dieu	Surgeon W. H. Austin.
Norfolk	† St. Mary's	Surgeon R. D. Murray.
Pensacola	† Private Hosp.	Act. Asst. Surg. F. N. Blount.
Philadelphia	† Jefferson Coll. H.	Pass. Asst. Surg. G. W. Stoner.
Portland, Me.	*	Surgeon E. J. Doering.
Port Townsend	* Private Hosp.	P. Asst. Surg. J. M. Gassaway.
San Francisco	* Mountain Lake	Surgeon E. Hebersmith.
St. Louis	* So. St. Louis	Surgeon H. W. Sawtelle.
Savannah	† St. Joseph's	Act. Asst. Surg. G. H. Stone.
Vineyard Haven	* Duke's Island	Act. Asst. Surg. W. D. Stewart.

* U. S. Marine hospitals. † Contract hospitals.

The Service has recently issued a circular showing more minutely than does the above table the various ports at which treatment is given to seamen, and what grade of medical officer furnishes it. From this we learn that the number of medical stations is 72. At these relief is given by regular medical officers in 24; by acting assistant surgeons in 30; and by contract surgeons in 18.

Passed Assistant Surgeon James W. Gassaway, of the Marine Hospital Service, has been relieved from duty at Port Townsend, W. T., and ordered to report for duty to Surgeon Fessenden, New York harbor. Assistant Surgeon Frank W. Mead has been ordered to take charge of the hospital at Port Townsend.

The new steamer, John M. Woodworth, which is to ply between the Battery and the Marine Hospital on Bedloe's Island, has arrived in port. It is a beautiful boat, sixty feet long, and modelled somewhat after the revenue cutters. It contains rooms for the officers, berths for sick patients, and every appliance necessary for prompt attendance on the sick. The steamer will act as a steam ambulance when necessary, and will take sick or injured seamen from the vessels as they come in.

Professor W. T. Wythe, M.D., died at his residence in California, June 26th, aged 33. He had for several years occupied the Chair of Anatomy in the Medical College of the Pacific Coast, and was much esteemed by his fellow-physicians.

Lord Shaftesbury at the Medico-Psychological Association.—The annual meeting of this association was held on July 30th, at the Royal College of Physicians, under the presidency of Mr. Mould, of Cheadle. There was a very full attendance of members from all parts of the United Kingdom. At the morning sitting a hearty vote of thanks was accorded to Dr. Tush, the retiring president, and the usual routine business was transacted. In the afternoon, the President read a carefully prepared and exhaustive address, introducing, among other topics for discussion, the question of providing detached cottage and villa residences for lunatics apart from the asylum proper; and Dr. Boyd read a paper upon the simplification of admission formalities.

The members dined together in the evening at Willis' Rooms, when they were joined by the Earl of Shaftesbury, Mr. J. T. Hibbert, M. P., and other distinguished guests. Lord Shaftesbury's health having been enthusiastically drunk, his lordship, in feeling terms, expressed the great pleasure which it gave him to meet a body of medical and scientific gentlemen of whose services he could speak with the greatest gratitude. Referring to the length of time during which he had been connected with lunacy work, he favorably contrasted the present state of things, both in public and private asylums, with that existing in former years, and alluded to the conscientious manner in which medical practitioners had discharged the duties imposed upon them by the Lunacy Acts, as proved by the evidence adduced before the Parliamentary Committee, which showed that 185,000 certificates had been issued to persons shut up upon those certificates, and though the committee sat for six months, yet they did not discover a single instance in which the patients had been shut up without good and sufficient reason. The present tendency (one to be guarded against in the public interest) was to let out everybody who was shut up, and henceforward to shut up nobody at all. It was to be hoped that, when measures of lunacy reform were decided upon, nothing would be done which would throw unnecessary impediments in the way of early treatment by a mistaken delicacy in regard to the "liberty of the subject." The two great principles to be maintained were a thoroughly efficient, permanent, and independent body of visitors, and every facility, under proper control, for early treatment. The toast of the House of Commons was responded to by Mr. Hibbert, M.P.

Inanition at Bellevue Hospital.—The house staff at Bellevue Hospital have made a complaint that their food is of such wretched quality and so badly cooked that it is impossible to live on the hospital fare alone. The young gentlemen have unfolded their troubles to the sympathetic ear of a *Tribune* reporter. Their meats were old and dry and fibrous; they eventuated uniformly into stews and hash, which depressed the appetite and paralyzed digestion. As a result of the diet thus forced upon the staff, about half of the number are worn out and nearly sick when they finally leave the hospital. Such fare is not offered in the other city hospitals; but a position at Bellevue is such a prize that the Commissioners do not feel inclined to remedy the trifle of an insufficient diet.

The house staff chose a poor time for their appeal to public sympathy. Dr. Tanner has created so wide an impression of the sufficiency of air and water, that few of the starving can get any sympathy until the forty-first day. Nevertheless, the young men at Bellevue work hard and faithfully, and they are entitled to receive something more than the cuisine of a third-rate boarding house.

The Night Medical Service in this city is now in full working order. The number of precincts in the city is thirty-five. The number of physicians who have been registered for duty on the night medical service is 329. This represents all the applicants for registration with one exception. The exception is that of a physician who was implicated in a recent criminal prosecution.

Original Lectures.

ON SOME POINTS IN THE MANAGEMENT OF

ASTHENOPIC SYMPTOMS IN EMMETROPIC AND AMETROPIC EYES.

A Lecture Delivered at the Manhattan Eye and Ear Hospital,

By O. D. POMEROY, M.D.

Lecture II.

(Reported for The Medical Record.)

Gentlemen :—The first topic this evening is hypermetropia. This is a condition of the eye which arises, probably, from arrest of development of the eyeball in which the antero-posterior diameter is too short. The lens and the cornea represent about the same refraction as that of the emmetropic eye. The eyeball being too short, it necessarily has insufficient refractive power. We have already learned that the emmetropic eye is in a state of absolute repose at the far point; that is, objects seen at a distance are accurately focussed upon the fovea centralis without the aid of muscular contraction. Light falling upon the emmetropic eye of a dead man, according to this theory, would reach an exact focus upon the fovea. That statement requires some modification. In a large majority of children, the eye, under atropine, will be found to be hypermetropic unless it is myopic. This is much more often the case than with adults. I have examined the eyes in quite a large number of adults under atropine, and have found that not more than five per cent. emerge from its influence without having been found to be hypermetropic or myopic. For producing this effect you may use a four-grain solution, and instil a few drops into the eye three times a day, for from one to three weeks, and thus put the muscle of accommodation into a state of absolute repose. In explanation of this fact of generally finding a lower refraction after atropia, I am inclined to offer the theory advanced by Donders, namely, that a certain allowance must be made for a species of normal tonicity of the ciliary muscle. He says from $\frac{1}{60}$ to $\frac{1}{40}$; that is, if the ciliary muscle is in a state of absolute repose, the eye would require a convex lens of from $\frac{1}{60}$ to $\frac{1}{40}$ to bring the rays of light to a focus upon the fovea. I would define hypermetropia, practically speaking, to be a condition of the eye in which refraction is lowered more than from $\frac{1}{60}$ to $\frac{1}{40}$ with the ciliary muscle in repose, by atropine or otherwise. The range of accommodation in the hypermetropic eye is frequently more than in the emmetropic eye, which will be an important element in our studies relating to the action of lenses in aiding vision in this class of cases. The hypermetropic patient has been so necessitated to intensify the action of the ciliary muscle to overcome the hypermetropia that he has gymnastically increased the power of the muscle. Likewise the power of the interni has been increased in a similar manner, which will account for the existence of convergent squint in some hypermetropic eyes; that is, the interni, by constant effort to equal the innervation of the ciliary muscle, become hypertrophied to such a degree that their opponents, the externi, are incapable of maintaining the eyeball in the proper position for binocular single vision, and the consequence is convergent strabismus in one or both eyes.

As to the use of glasses in hypermetropia. We started with the proposition, in speaking of emmetropia, that to read comfortably for any given length of time, at the usual distance, the patient would be required to call forth a little less than one-half the range of accommodation. The hypermetropic eye frequently having a greater than normal range of accommodation, can, on account of that, often work without glasses with perfect comfort. For instance, the range of accommodation may be $\frac{1}{3}$; if we divide that by two, we have $\frac{1}{6}$, which is more than needed. Then if he has a hypermetropia of $\frac{1}{12}$ to $\frac{1}{18}$, the reading distance will be removed to the proper point—namely—thirteen or fourteen inches. Moreover, in the management of hypermetropia we meet with precisely the same question that confronted us when studying the management of emmetropia—namely—ciliary muscles differing greatly in contractile power. By the rule already laid down, to use one-half of the range of accommodation, you can see that some cases would require glasses and others would not.

The management of manifest hypermetropia in very young subjects. I will speak of this separately. A very large proportion of young people have, as we previously stated, a certain amount of hypermetropia. Frequently it is facultative; that is, they will see just as well without convex glasses as with. It comes to be a question whether you will correct their ametropia or not. If there are no asthenopic symptoms, do not use glasses; if there are, use them. But you will frequently find, after the ciliary muscle becomes rested on account of the use of the spectacles, that the glasses will be thrown off as something not to be longer tolerated. I have in mind a case: a young man, sixteen years old, had manifest hypermetropia of $\frac{1}{40}$ and asthenopic symptoms. I prescribed $\frac{1}{40}$, and he wore the glasses a year with comfort; they began then to worry the eyes and he found that he worked better without than with them, and I therefore told him to discard them. He did so, and ever since has worked comfortably without the aid of glasses.

In a patient of middle age, I should, as a rule, neutralize all the manifest hypermetropia, and let him wear glasses for distance, unless he found, after awhile, that he was just as comfortable without glasses as with them. But if he previously had asthenopic symptoms, he probably would bear to use the glasses constantly.

At the near point he may use glasses which nearly equal or even exceed the total hypermetropia, and the glasses can be determined by the rules which we adopted in fitting glasses for presbyopia—namely, take the lens which corrects the manifest hypermetropia, and see what the range of accommodation is; if it be less than $\frac{1}{8}$, find by the plan previously stated what glass will bring the near point up to eight inches; this, added to his hypermetropic correction, will give the proper reading glasses.

CONVERGENT SQUINT AND HYPERMETROPIA.

I will say a few words regarding the management of convergent squint in hypermetropia. A good deal has been attempted in relieving convergent squint without tenotomy, especially if it is what is called periodic squint, the earlier manifestation of strabismus. It is a fact that many young patients who occasionally squint may have convex glasses adjusted to their eyes which will relieve the tension of the interni so completely as to cause them to use their muscles so moderately as not to give rise to a squint at all. But that plan has not succeeded as well as was anticipated. I have coming to the clinic a patient in whom I had corrected the convergent squint by a tenotomy. Afterward the squint returned. The eyes now are perfectly straight while he wears glasses, but if he leaves them off even for a few minutes the squint returns.

GLASSES AFTER TENOTOMY FOR CONVERGENT SQUINT.

As to the strength of glasses to be used after tenotomy, I do not always use correcting lenses after tenotomy for convergent squint, even in hypermetropia. If there is a considerable degree of hypermetropia I always do. In young children, who are very prone to relapses after tenotomy, I always use a correcting lens, *provided* I find a considerable degree of hypermetropia. That is usually satisfactorily found by the ophthalmoscope only. I am in the habit of making a diagnosis of all the hypermetropia which may be developed by the ophthalmoscopic examination, and fitting the patient with glasses thus found. I direct them to be worn for a longer or shorter period of time. A case will illustrate this point. A child four years of age was operated upon by me for convergent squint. The eyes became straight, but relapses occurred several times. I caused her to wear glasses which neutralized all the hypermetropia diagnosticable by the ophthalmoscope. As long as she wore the glasses her eyes were straight; but leaving them off for a few hours only, the squint would return. I directed that glasses be worn constantly, but to leave them off when it could be done without causing a return of the squint. After three or four months the parents came with the joyful intelligence that the child was able to discard the glasses without provoking a return of the squint. Up to the present time the eyes remain straight. Even if you overcorrect the hypermetropia in little children, I do not know as it does any special harm. I do not now recall a case in which pain, lachrymation, or appreciable discomfort has resulted from wearing glasses which were too strong to correct the hypermetropia. The worst they can do is to induce an artificial myopia.

ATROPINE IN CONVERGENT SQUINT IN THE HYPERMETROPIC EYE.

Atropine has been used to correct the convergent squint of hypermetropia. I think Dr. John Green, of St. Louis, kept the eyes of a patient under the influence of atropine for from one to two years, with the view of curing the squint. So long as he used the atropine the squint was relieved. In some cases, however, this good result was not obtained. After the patients recovered from the atropine the squint commonly returned; so I believe he has abandoned the device of curing the strabismus in this manner. I do not by any means find that atropine will prevent even periodic squint, except very infrequently. Theoretically it may do so, because it relieves the interni from the extra tension which develops the squint.

THE VISION OF HYPERMETROPES.

If the patient has a high degree of hypermetropia, you must not expect to bring vision entirely up to the normal $\frac{20}{20}+$. I have previously hinted at the fact that the hypermetropic eye exhibits signs of arrest of development, and functionally it will often be found faulty. I think these persons have a smaller optic nerve and a less development of the retina than exists in the normal eye. I have often fancied that the visual field was a little limited in high degrees of hypermetropia.

ASTIGMATISM IN HYPERMETROPIA.

In managing the astigmatic symptoms of hypermetropia, a little skill is required. I think I generally find the astigmatism about the same before the use of atropia as after. Sometimes it may be somewhat increased, but the amount of astigmatism, certainly in adults, which is revealed by trial glasses, before atropia, is a fair guide to go by. You have frequently heard it said that such a patient has too small an amount of astigmatism to be worthy of correction. This is frequently the case in hypermetropes, but not often in myopes. Here we follow the law already stated, namely, if we have a vigorous ciliary muscle it may overcome slight degrees of astigmatism without trouble. I will state a case. A gentleman, 46 or 47 years of age, had a small amount of astigmatism ($+\frac{1}{60}$), which was diagnosticated at that time. He asked for glasses on account of moderate presbyopic symptoms. I told him that his right eye was slightly astigmatic, but that I thought it would not give him any trouble, and advised him not to go to the extra expense of a cylindrical glass. He went away, used the glasses prescribed for about a year, and then returned, saying that his right eye had pained him somewhat, and that it watered. In other words, it began to show asthenopic symptoms. I then saw that it was necessary to correct the hypermetropic astigmatism, and he has had no asthenopic symptoms since. You will conclude by this that at the beginning it may be a kind of experiment as to whether or not you will give the patient a glass that will correct the hypermetropia. Of course, with only a moderate degree of hypermetropia and a strong ciliary muscle, he would prefer to avoid glasses.

Some years ago, by the advice of a distinguished gentleman in Berlin, I purchased a set of cylindrical lenses ranging as high as $\frac{1}{40}$. But since that time it has been found that this number is much too strong for some cases, especially for myopes; and even in hypermetropia we find occasion to use a cylindrical lens as weak as $\frac{1}{60}$. Some go much finer than that, but I can hardly see any proper indication for so doing. Insufficiency of the interni in hypermetropia may be managed precisely as in emmetropia.

MYOPIA.

In myopia there exists a condition exactly the opposite to hypermetropia; that is, the eye-ball is too long instead of too short. It is more than that. It is frequently, indeed almost always, a more or less diseased eye. The length of the eyeball is due to an ectasia or bulging of its posterior portion. This may be a thimble-shaped projection located in the region of the fovea; it may reach the border of the disk, or any other portion of it, or the whole may be included. It may extend even to the equator of the eyeball. You will perceive by this why we are so uncertain in our diagnosis of the refraction of a myopic eye by the ophthalmoscope. It is extremely difficult, if not impossible, to diagnosticate exactly the refraction of the fovea centralis without the aid of blood-vessels, which are not found in this region, and the best I can suggest is to observe the refraction as near the macula as vessels are found. This refraction may be a little more, perhaps a little less than that determined by the trial-glasses.

The cause of the bulging of the eye in myopia is a disease which Graefe called sclerotico-choroiditis posterior, and is almost always accompanied by posterior staphyloma. It produces changes in the choroid resulting in atrophic patches here and there, stretches the retinal tissue, sometimes causing detachment, and induces quite a variety of retinal disturbances. So in a large number of cases of high degrees of myopia you will find that amblyopia enters largely into the problem of the selection of glasses. In consequence of this bulging of the eyeball, it presses rather heavily upon the fatty connective-tissue cushion at the posterior part of the orbit, and hinders mobility of the eyeball in a purely mechanical manner. In consequence of this the ocular muscles, notably the interni, will be found quite insufficient to proper mobility of the eye.

Insufficiency of the interni is quite characteristic of myopic eyes, and it sometimes exists to the extent of causing divergent squint. In hypermetropia, you remember, we occasionally have convergent squint. This is an element which requires careful consideration when glasses are adjusted.

WHAT GLASSES SHOULD BE GIVEN TO A MYOPE?

It has been laid down as a rule in many of the books, including Donder's, that if the range of accommodation in the myopic eye is normal, you can give the patient glasses for distance that neutralize the myopia, and which may be worn for constant use. This rule, very frequently, is not to be relied on. I can explain the fact only by referring to two theories.

The ciliary muscle in myopia is frequently quite weak. In general terms you will find that a myopic eye works much more comfortably with the accommodation considerably relaxed.

Again, in myopia, we have to deal with what is extremely troublesome; that is, any disturbance of the relative accommodation. Take, for instance, a myopia of one-sixth; the patient will read with the far point at about six inches; his accommodation will be almost completely relaxed, but the interni represent a convergence of six inches. He may have done this so long that he will do it with comparative comfort. You can readily see that this is an artificial condition, due simply to a long-continued habit, and it is extremely difficult to cause the patient to use his eyes under different conditions. Now correct the myopia and then notice the change. At the *far* point he will see objects with relaxed accommodation, and instead of the interni converging at a point six inches distant, the parallelism of the eyes must be retained, which necessitates a prodigious tension of the externi, and thus gives very great discomfort. To avoid this complication of changed relative accommodation, we select glasses for distance which do not wholly neutralize the myopia. I have already stated that in myopia you must attend to the condition of amblyopia.

Do not forget for a moment that the myopic eye is often better able to read fine print for a longer time than even the emmetropic eye, because it has, from the mere fact of its myopia, a *magnifier* before its eye, and the interni are so well accustomed to this condition that they give little or no trouble, even in excessive convergence.

When I tell you to allow the patient to have a glass that neutralizes the myopia, to wear constantly for all kinds of work, he should find it comfortable; if not he must lay it aside. In any event you may neutralize all the myopia with a glass which is occasionally used for distant objects only. Now, for glasses which he can wear constantly with some comfort, I should say select those which will cover points from six to ten feet distance. They will enable distant objects to come out to a reasonable degree of clearness, and will not strain the muscle of accommodation unduly in looking for a few moments at near objects. What shall we do for reading glasses? If the myopia is from one-eighth upward I should not give reading glasses at all. *Some* patients with myopia one-sixth read better without than with glasses. But if you have concluded to give glasses for reading it will be for the higher grades of myopia; give those which only remove the myopic far-point a little distance away. A high degree of myopia should not have the reading distance pushed beyond from seven to ten inches. But the element of empiricism comes in here very strongly.

On the subject of high degrees of myopia and ability to do good work without glasses, I would cite a case of this kind. In myopia, vision in one eye is sometimes very poor, or one eye may be much more myopic than the other. The myope will by preference, then, use the best eye. While riding in a street car some time since, with a professional gentleman and his wife, we noticed a man opposite us who was reading a newspaper held not more than two or three inches from the eyes. I remarked that he was reading with only one eye, and the doctor's wife being rather incredulous upon that point, took the pains to make the necessary observation, when she found, sure enough, that the man had one eye widely deviating from the object, while the other was fixed upon it. These patients will frequently do that, especially if they have a high degree of amblyopia. You will remember that I told you watchmakers could work with a single two-inch lens without fatigue for many years; the interni, of course, not being engaged, the proper amount of accommodation is readily adjusted.

In myopia or hypermetropia, if the eyes have different degrees of refraction, I would follow this rule: if the difference between the two eyes is more than $\frac{1}{20}$, I would fit the best eye; that is, the eye which has the least myopia or hypermetropia, and the best vision, giving the same glass for the other eye. If the difference is less than $\frac{1}{20}$, I should fit each eye separately. Considerable trouble will be required on the part of the patient to adjust for comfortable vision even here. You have two eyes requiring quite dissimilar glasses; you have two retinal images differing from each other in size, and these have to be fused into one image by a mental process. In myopia, select the weakest glass that will correct properly, otherwise the accommodation becomes unduly intensified.

Several years since I fitted a patient with glasses for myopia and astigmatism. Having no minus glasses weaker than $\frac{1}{40}$ at that time, I used that, and it seemed to correct the error well enough. He used the glass something like a year, and then came back, saying that his eye began to pain him. Since the first fitting of the glasses, I had had made for stereopticon purposes a set of cylindrical lenses running up to $\frac{1}{96}$. Looking his case over carefully, I found that $\frac{1}{96}$ cylindrical corrected his myopic astigmatism perfectly, and all the asthenopic symptoms promptly disappeared.

Insufficiency of the interni in myopia is extremely important, because it frequently develops into divergent squint, as well as produces asthenopic symptoms. If a squint is present, you may operate, and usually in divergent squint the interni must be advanced either one or both. But if the insufficiency is moderate, say 10° to 15°, you may correct that by prisms with the bases placed inwards. In selecting the prism you will be guided by the rule already laid down, and that is, use about one-half the prismatic power which represents the insufficiency at the far point and distributed equally between each eye.

Some ten years ago, as near as I can recollect, Pagenstecher, of Wiesbaden, and others, practised division of the external rectus muscle to relieve the asthenopic symptoms resulting from insufficiency of the interni. I have done the operation in only two cases, both moderate degrees of myopia and noticeable insufficiency of the interni, not sufficient, however, to spoil binocular single vision, and in each case I relieved the asthenopic symptoms, but I had the same experience many others have had—namely—whenever the patients looked far in the direction of the divided muscle, they had a certain amount of diplopia. In my cases this did not produce serious discomfort, but with this possibility in view, and on account of the large experience of others, which condemns the operation, I have abandoned it.

Another means of relieving the fatigue and ciliary neuralgia of myopic eyes is atropine. For this purpose a four-grain solution may be used three times a day, or sufficient to put the ciliary muscle completely at rest. Of course smoke or blue glasses may be used while this is being done.

A myopic patient should not bend over his work. He should do nothing to cause blood to go in abnormal quantities to the region of the eye. Again it may be used as an argument in favor of the use of glasses, that the patient can then hold his head erect and thus prevent the congestion of the eyeball that is likely to increase the previously existing disease, consequent on bending over his work. Dyer's plan is applicable here as in hypermetropia.

In myopia you may use a very weak concave glass to slightly change the relative accommodation.

Sometimes you will be extremely annoyed to find that the myopic eye refuses every form of spectacles. I would explain that fact upon the theory that the patient, for some reason not understood, cannot bear to have his relative accommodation changed; not even by the use of prisms which would retain, in a measure, the same condition of relative accommodation that previously existed.

From what has been said you will conclude that the matter which we have been studying is not one of exact science; that is, we are obliged, as yet, to partially recognize the empirical element. That glass which is worn comfortably by the patient, and relieves his asthenopic symptoms, is, evidently, the proper glass for him to wear.

◆

Help for Red Noses.—When alcohol, or the force of circumstances, has brought to a man a red nose, it has generally been considered irremediable. He tries, perhaps, a few bran poultices, and then abandons himself to the inevitable rubescence. Mr. Malcolm Morris reports (*Brit. Med. Journ.*) considerable success with acne rosacea, when thus affecting the nose, through the use of linear scarifications. He had tried this method in the way recommended by Mr. Squire as a remedy for port-wine mark, but failed of doing any good. Applying it to other conditions, however, he had much better success. His plan is to scarify the affected part in parallel lines, allowing some blood to flow. He repeats the operation from ten to twelve times.

A CLINICAL LECTURE ON TETANUS.

By JOHN A. OETERLONG, A.M., M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE IN THE KENTUCKY SCHOOL OF MEDICINE.

(Reported by A. H. Kelch, M.D.)

M. M——, German, married; stone mason; was injured two weeks since on the left leg, receiving a trifling bruise that merely scraped off the skin, and which is now entirely healed, with a slight degree of pigmentation. Five days since he first noticed some stiffness of the jaw; he then began to suffer with severe pain in the breast, about the inferior extremity of the sternum, shooting directly through to the back. Then followed difficulty of swallowing, which has since increased; dyspnœa and stiffness of the lower extremities.

Patient somewhat above the medium; well nourished. Previous to present illness healthy and strong. Pulse, 72; temperature, 99. He is somewhat stupid and drowsy from chloral and bromide of potassium, which have been freely used; pupils normal; he occasionally spits blood, mixed with tenacious saliva; jaws rigid; body and extremities extended and rigid.

According to the statement of the house physician, Dr. Hayes, the patient had a tonic spasm every twenty minutes or half hour when first admitted, until the remedies prescribed began to take effect. During these spasms he bit his tongue rather severely, and it is from this source that the blood is derived which he occasionally expectorates.

As a general thing those subject to tetanus do not sleep much, but during sleep the rigidity is more or less relaxed. The disease is not only characterized by rigidity, but there is also spasm, never entire relaxation. Occasionally, at varying intervals, dependent upon circumstances, it becomes violent and painful. As in this case, it usually begins about the jaws and neck, and then involves the muscles of the back, the sides, and the abdomen, and these contract with such tremendous violence that they are sometimes torn across, and in post-mortem examinations they have been found severed, thus showing how extremely violent the contractions have been. As a general thing the mouth is clogged with viscid, glutinous sputa. There is dyspnœa, especially in paroxysms, that is occasionally aggravated to the degree of apnœa. This is in part dependent upon spasm of the diaphragm, in part upon spasm of the glottis, and upon the rigidity of the muscles of the jaw. There may be comparative voicelessness. The words are not enunciated with full voice, but are squeezed out, so to speak.

The pulse is usually greatly accelerated, but in this case, as I have already stated, it is now only 72. The temperature is generally elevated, and may become exceedingly high, rising, after a violent spasm, to even 105°. In fatal cases it is noticed that the temperature rises very considerably after death, as it does in some other diseases, for instance, cholera. As a rule the skin is very hot, and it is often bathed in profuse perspiration. It has been said that in tetanus there is no true fever. In mild cases there may not be, but in those of a severe type there is certain to be fever, unless the case should suddenly terminate fatally, in a few hours after its inception, as sometimes happens. Greatly increased reflex excitability is another symptom. Sometimes a jarring of the floor, or a breath of air, throws the patient into a violent spasm; even the contact of the bedclothes may produce the same unpleasant effect.

The word tetanus is derived from a Greek word meaning "to stretch," and is a very appropriate term, for as a general thing it is the extensor muscles that become rigid. The forearms are extended upon the arms, and the fingers may be extended upon the hands. The muscles of the back and the neck are tightly drawn, and during a violent spasm, as also sometimes occurs in meningitis, the patient's body forms an arch, supported by the head and the heels, this being known as opisthotonos.

Recent investigations make it probable that tetanus is inflammatory in character. It is what some writers call a central myelitis, that is to say, the gray matter is the seat of the lesion; this does not necessarily limit itself to that part of the cord, but it is the starting-point of the morbid process. Occasionally the white matter is implicated, and sometimes even the membranes.

The anatomical changes that take place are very various. They may consist of simple redness or engorgement of the vessels; there may be a certain amount of exudation, even some disintegration of the gray matter. But many writers will tell you that no lesion whatever has been found on post-mortem examination, and doubtless they tell you the truth, as far as they know. Their statements amount simply to this: that they have discovered no lesion of the cord. The probability is they either have not had the means of making a complete investigation, or they have neglected to do so; at any rate, that a thorough and exhaustive examination of the spinal cord was not made in these cases. Lockhart Clark, Dickinson, and Surgeon-General Hammond have shown very conclusively, I think, that tetanus is, in fact, an inflammatory disease of the gray matter of the spinal cord. The portion of the cord involved (whether upper or lower) depends upon various circumstances, perhaps upon the cause of the disease. There are two varieties: traumatic tetanus, the result of an injury, and idiopathic tetanus, which occurs independent of any trauma. When the disease comes on idiopathically it usually manifests itself as it did in this case, for I cannot believe this little bruise, which occurred two weeks ago, has had anything to do in producing this malady. Perhaps if we examine him carefully we will find he has been exposed to cold and damp. I have known the disease to occur, and authors will tell you it may be developed, in consequence of exposure. Indeed, exposure to the vicissitudes of the weather is, next to trauma, its most frequent cause. Hence the disease is of greater frequency in the very cold and very warm zones. During the late war, according to Hammond. it was noticed that after a very cold or damp spell of weather the army reports furnished to the surgeon-general gave an increase in the proportion of cases of tetanus. The disease is said by some to have been produced by fright. It may be so, but I doubt it.

On questioning the patient, I find he has been lying down to rest upon the cold ground after his work was done, and the disease may have originated in that way.

As to the time between exposure and the occurrence of the symptoms, I can tell you nothing. I lack the facts to establish even a general duration of this period. It cannot be very long. This man exposed himself on Tuesday evening, and on the following Friday night the first symptoms set in. The disease sometimes proves rapidly fatal. It has been known to cause death in a very few (eighteen and even five) hours. It is a favorable indication when it runs a protracted course, but cases have been known to last many days, and then terminate fatally. The average duration in fatal cases is from three to five days. The prognosis is more favorable in idiopathic cases than in traumatic. In traumatic cases the symptoms are somewhat determined by the location of the injury; for instance, if this is somewhere about the upper extremities, the symptoms are likely to manifest themselves first in the neck. If in the lower extremities, the rigidity may first occur there, and it has been found that the nerves running from the part injured are in a state of inflammation; so that whatever be the exact mechanism of the disease, it seems that some morbific influence originating in the wound is transmitted along the nerves to the spinal cord. It has been stated that there is, perhaps, a morbid condition of the blood, and that this morbid condition results in certain changes in the spinal cord, and so affects it as to increase its polarity, rendering it unduly excitable. There is no doubt that the reflex excitability of the cord is greatly augmented, but there is no evidence that there is any blood-change that induces this condition of the cord. All we know is, that under certain conditions the spinal cord takes on an inflammatory action, and that this inflammatory action is first developed in the central gray matter; that it is not necessarily limited to that part, and that the congestion and irritation of the parts involved result in undue reflex excitability. You must remember that the cord generates nervous force, as well as conducts impressions, and it is especially the first of these functions that is implicated in this disease.

Is there any disease with which tetanus may be confounded? You may suppose that owing to the occurrences of opisthotonos it might be mistaken for cerebro-spinal meningitis, and I have no doubt that it has. I believe cases have been reported as tetanus which, in reality, were cases of acute spinal meningitis; but in the latter disease, as a general thing, the mind becomes involved, while in tetanus the mind is clear, and there are no head-symptoms. I leave out of consideration those very rare cases where there is coma, which, in some of the cases, must have been produced by the medicines given. You notice this man is drowsy and stupid. This is not due to the disease, but to the chloral and bromide of potassium he has been taking. Many cases of tetanus have been treated with opium, and in these cases there is a likelihood that the coma was rather due to the drug than to the disease. As a general thing, then, there are no head-symptoms, the mind being clear to the last, but there may be coma, or a certain degree of delirium, independent of any medication whatever, and the probability is that this is developed in consequence of interference with respiration, by which the function of hematosis is necessarily very much impeded. This only happens in cases where the spasms are violent and frequent. The circulation in the brain in such cases is undoubtedly more or less impeded. Tetanus has been confounded with strychnia-poisoning. There is no morbid condition that so closely resembles tetanus as strychnia-poisoning, and because the symptoms of the latter are produced by a substance acting through the blood, it has been argued that tetanus is also produced by some blood-poison, but we have no facts to support the hypothesis. In strychnia-poisoning, the history of the case is not that of tetanus. If, for instance, you have to deal with traumatic tetanus, the existence of an injury received some time previous would be one of the points in the differential diagnosis.

Then, in tetanus there is apt to be languor and lassitude, constituting a prodromic stage, whereas in strychnia-poisoning there is a degree of exhilaration and restlessness that is quite foreign to the period of invasion of tetanus. Furthermore, tetanus first manifests itself by rigidity of the muscles of the neck and by stiffness of the masseter muscles. You see in this case I cannot open the patient's jaws at all, and this inability was the first thing he complained of. In strychnia-poisoning the first indication of rigidity is commonly in the lower extremities, although there are some exceptions to that. I remember having taken strychnia some years ago in pretty large doses, and the first indication of rigidity from the drug was *in the jaws*. I noticed that in speaking I had some little difficulty in pronouncing certain words, and also in managing the facial muscles, and I felt, in addition, a degree of energy that was even beyond that which was usual with me in a state of perfect health. One day, when I had taken a fuller dose than common, I noticed some little stiffness of the muscles of the neck, and at one time, very suddenly, a decided difficulty in getting my breath. These symptoms passed quickly away on discontinuing the drug. I mention this in order to show that even slight cases of strychnia-poisoning may exceptionally be manifested first in the jaws and in the neck.

A very excellent *résumé* of the points involved in the diagnosis between idiopathic tetanus, hysterical tetanus, and strychnia-poisoning, will be found in H. C. Wood's Materia Medica, Therapeutics, and Toxicology. In making the diagnosis between tetanus, idiopathic and hysterical, the sex, the hysterical temperament, and the history of the case go far to establish a correct conclusion.

The prognosis is grave even at the best. A certain number of cases will get well no matter what is done, and a certain number will die.

In looking over the history of the therapeutics of tetanus you will discover that a great number of medicines have been used, and recoveries have been reported under any and all of them. On the principle that the disease is inflammatory in character, there are certain remedies that ought to be used. On the principle that the prominent symptom must be treated, and that spasm is the trouble that proves most dangerous—death, I have no doubt, often occurring from spasm of the glottis, and it has been suggested that death has occurred from spasm of the heart—acting upon this principle, I say, there are certain remedies that suggest themselves on theoretical grounds, and my own experience warrants me in saying they afford the best prospects of recovery. They will not always establish a cure, nor can I say in what proportion. Nevertheless I believe I am entitled to say that the plan of treatment I am about to mention is, in the present light of knowledge, the best that can be proposed.

I believe that ice-bags applied to the spine, as recommended by Hammond, constitute a most important and beneficial application. They should be applied along the whole length of the spine and kept up until the disease has yielded. We know that cold lessens congestion, because contraction of the vessels diminishes the amount of blood in them, and cold also lessens reflex excitability. Thus it fulfils a double indication. Among internal remedies the best are bromide of potassium and chloral. I would prefer to give them in combination, and they should be given in full doses. The patient should be kept under their influence continually, and when the disease shows evidence of yielding by relaxation of the masseter muscles and lessened stiffness about the jaws, and the tendency to retraction of the head and the occurrence of spasm grow less, then and only then should the doses be lessened and the interval lengthened. Another remedy has been used with a great deal of success, although the experience of clinicians respecting its efficacy is decidedly conflicting, and that is the calabar bean. I think a good way to administer it is in the form of an extract, one grain by the mouth every two hours until its peculiar effects have been manifested in the form of muscular relaxation. A better plan, perhaps, after which to give it is in the form of hypodermic injections (gr. ⅛) of the extract, repeated every two hours until the patient is thoroughly brought under its influence, and then afterward keep up its effects by the continued dose by the mouth.

Should anything be done in this case to lower the patient's temperature? I do not think it necessary to do anything beyond what I have already suggested. This patient's temperature is about 101° at present. Under the continued doses of the bromide and chloral his temperature will go down still more. The fever arises, in part, from the inflammatory trouble in the cord, and in part it is due to frequent and severe spasm. As the frequency and violence of the latter are diminished the temperature falls.

The characteristics of the temperature in tetanus are somewhat of an aid in the diagnosis. Ordinarily in acute diseases the temperature falls before death, but in tetanus, as dissolution draws near, the temperature rises, and increases still more a few hours after death.

There is another remedy that ought to be used, and used freely, for several reasons. Statistics show alcoholic stimulants to give very good results. A very considerable number of cases treated by alcohol alone have recovered. Dr. Yandell, in his report of a large number of cases of tetanus treated by alcohol, gives a number of cases of recovery, amounting to eighty per cent. These cases were collected from the current medical literature of the day. All authors agree that the action of stimulants in cases of tetanus is beneficial. It is found that they allay the reflex excitability, they help to overcome the great sensitiveness of the surface, they tend to produce quiet and sleep, and aid in a certain degree to keep up the strength, and I am convinced the patient should have them, and have them freely. I will not pretend, however, to go over all the remedies that have been used in the treatment of this disease. Their number is exceedingly great, and, as I have often told you, whenever numerous remedies are recommended in the treatment of a disease, it is safe to conclude that none do much good.

Perhaps I can entertain and instruct you by relating a few other cases of tetanus that have come under my observation and which recur to my memory. The first case was that of a very large and muscular man—a perfect giant. He had worked out in the snow and cold, and as a result of the exposure he was attacked with tetanus in its worst form. It made such an impression upon me I shall never forget it. That strong man was bent back like a bow. He had a quiet and placid face, as the majority of very large men have, but it became frightfully distorted during the spasms.

The "risus sardonicus" became painfully marked; the nostrils became distended, the upper lip drawn up and the corners of the mouth backward and upward, causing that sardonic grin which has given rise to the term. The spasms occurred with terrible frequency and violence. He was treated by immersions in the warm bath, where he was kept by the hour, and stimulants were freely given. That was long before anybody knew anything of bromide of potassium, chloral, and calabar bean. He died at the end of ten days in a spasm (as I believe) of the glottis. Another case was the first in which chloral was used this side of the Alleghany mountains. In 1869 a bottle of chloral was sent to Prof. S. P. Breckenridge, then a colleague of mine, and through his kindness I was enabled to use the drug probably for the first time in the State of Kentucky. This case was of traumatic origin. The patient had suffered a severe injury of the foot, and the case commenced with symptoms of decided severity, but by the use of chloral, ten or fifteen grains every three hours, they were kept in abeyance for days and days, and I believe the man stood a pretty good chance to get well, when I was called away on business, and the case was put in the hands of another physician, who simply treated the case with poultices wrapped around the leg to allay the inflammation, but this did not prove very effective and the man died.

A third case occurred in a woman upon whom a resection of the tibia had been made. In that case the granulations were exceedingly exuberant. About the second week after the operation she showed symptoms of tetanus. The case was treated by pretty free administration of bromide of potassium and chloral, and the local application of nitrate of silver. It seemed in this case that the starting-point of the trouble was the excessively sensitive granulations, and it is very certain that from the moment the irritability of the nerves lying exposed in the granulating surface was reduced by contact with the nitrate of silver, the patient began to improve.

Another very interesting case was that of a little child that I had delivered with instruments at a little more than seven months. It was fully an hour before respiration could be established, the skin was excessively thin and sensitive, and in the delivery the head had to be compressed very considerably, the mother being over forty and a primipara. Although we expected the child would die, respiration was finally established, and at last the little thing gave evidence of an intention to stay awhile. On the third day it was attacked with trismus or the tetanus of new-born infants, and it had a very decided case of it.

I mention it to you in this connection, not because "tetanus neonatorum" is very unusual, nor because this case presented any extraordinary features, but because it affords me an opportunity to suggest to you a line of treatment that promises to be successful in similar cases. I treated that child by means of injections of chloral hydrate per rectum, which allayed the spasms, and the little one at length recovered. I have since treated a number of such cases in the same way with good results.

Many physicians at the present time believe that the tetanus of new-born infants is due to some injury of the umbilical cord. That there are nerves in the cord and in the neighborhood of the umbilicus, I think is pretty well established at the present time, and high authorities of the present day have expressed the opinion that trismus depends upon the surgical injury of cutting the cord. But be the cause what it may, I am sure nothing has given me better results than rectal injections of one or even two grains of hydrate of chloral. It has the advantage that there is no struggling of the little child in swallowing the medicine, which is difficult to accomplish at the best, and especially where there is rigidity of the jaws.

Tetanus sometimes occurs independent of external injury or exposure to cold, in connection with the parturient state. This is called puerperal tetanus. The probability is that tetanus under such circumstances is of surgical origin, that is to say, the cavity of the uterus is in the condition of a wound—it is a raw, abraded surface. This is an idea advanced many years ago by Sir James Simpson, who said that puerperal fever is identical in its nature with surgical fever, and I have no doubt that it is. Or it may arise in connection with inflammatory processes in different localities, the spinal cord becoming implicated in the morbid process just as the lungs or other organs are in other cases.

Original Communications.

THERAPEUTICS AS BASED ON THE STUDY OF TENDENCIES.

By H. H. KANE, M.D.,

NEW YORK.

Certain terms, vaguely foreshadowing great truths, have for years found place in medicine, and while answering a certain purpose, have yet served to obscure the proper understanding of those facts the superficial recognition of which called them into existence. So long has this been so that to-day we know as much of the shadow and as little of the substance as did our ancestors. It has been, and is, so convenient to refer all peculiar action of drugs, foods, and atmospheric changes to an idiosyncrasy, and to do away with all puzzling details of investigation by classing certain individuals with certain ill-defined resemblances under the head of imaginary temperaments, that any thoroughly scientific study of the underlying causes of these peculiarities has never been made. This is the more surprising when we consider that the tendency in medicine of late years has been to modify the treatment of disease according to the conditions of the individual. This is well shown by the recent discussion regarding the propriety of bleeding and other reducing measures in the treatment of pneumonia, and the different conclusions arrived at with reference to its employment in hospital and private practice. This is simply a gross class distinction, but one that shows how professional opinion is tending. There are, however, finer distinctions and certain general principles underlying the whole subject that are neither recognized nor considered, but that are absolutely called for by the present state of the other departments of medical science.

The term idiosyncrasy has come to mean, in medicine, a peculiar personal susceptibility to some food, atmospheric change, odor, or drug—more often the latter. We all know that certain persons are rendered "nervous," delirious, tetanic, and are occasionally convulsed, by doses of morphia that in the average individual would have almost no effect, and if any, that of an hypnotic or anodyne. We have all either seen or read of individuals in whom quinine, aconite, arsenic, ergot, bromide and iodide of potassium, chloral. and many other drugs, produce cutaneous eruptions, affections of the eyes and ears, vertigo, nausea, syncope, convulsions, and other actions that in the majority of people are never seen.

There are national as well as individual susceptibilities—in some cases peculiar effects being produced, in others simply a peculiarity with reference to the amount of the drug necessary to produce its usual effect. This we see with regard to arsenic, mercury, opium, hashish, and other drugs.

There are likewise idiosyncrasies with reference to foods (partridge, wild duck, lobster, shell-fish, and certain kinds of vegetables), to the inhalation of certain vapors and dusts (as of ipecac, asafœtida, and valerian; the pollen of certain plants; the odor of cats, dogs, goats, etc.), contact with some plants (as sumach, ivy, etc.).

There are national and individual idiosyncrasies with reference to disease as well as to drugs, and there is of necessity a direct connection between the two. This fact—personal and national, or class susceptibility—was recognized and spoken of some years ago by Prof. A. H. Garod.

It is, he says, the habit of physicians to note carefully the physical signs of disease, while but little attention is paid to idiosyncrasy. Ravaging epidemics, endemics, and hereditary diseases affect some constitutions rather than others. The result is the development of peculiarities in the natives—the survivors of all countries—and these peculiarities are dependent, in large measure, on the natural selection thus insidiously and constantly at work. Visitors in Rome and Naples are but too likely to be attacked with fever of a typhoid stamp, in the same localities where the Italian enjoys perfect health on account of his being the offspring of those who in times gone by have resisted, by constitutional peculiarity, the malarial atmosphere. What qualities is the early death of the drunkard weeding out? What phthisis? The true American of the United States differs conspicuously from the Englishman. How is this so? These, adds Dr. Garod, are problems which deserve more attention than they receive.

As is seen, he ascribes, and very justly, I think, national idiosyncrasy to the sum of individual idiosyncrasies, the survival of those least antagonized, giving the preponderating tint to the whole picture. This applies to normal and abnormal, mental as well as physical peculiarities.

There are individual idiosyncrasies that, with certain modifications due to intermarriage, surrounding circumstances, etc., pass from generation to generation, and finally terminate in some distinct tendency. Those who have been for years the medical adviser of a family have noted how a certain peculiarity, physiological or pathological, physical or mental, in one generation, has been increased, modified, or obliterated in the succeeding generation or generations.

To arrive, then, at a proper understanding of this very important matter, it is absolutely necessary that there should be a careful study of human pedigree. The breeders of blooded horses and short-horn cattle are fully alive to the value of a carefully kept pedigree of their stock. The study of human pedigree should be much more thorough and extensive. There should be kept a careful record of diseases, cause of death, idiosyncrasies, advanced tendencies, general conformation, and the material introduced by intermarriage, as also the person's surroundings, social, mental, moral, and physical.

An autopsy should be had in every case where there is any doubt as to the cause of death. In this manner the tendencies to death in families and in individuals could, after a time, be learned with some accuracy, and such tendency be possibly combated. In every family we find certain members who show a peculiar susceptibility to disease of certain organs. We say that they are predisposed. Thus, exposure to cold or wet will almost invariably produce in one neuralgia, in another bronchitis, in another nephritis or cystitis. It is simply a tendency, and is analagous to that aggravation of *existing* disease by atmospheric changes, and chemical or mechanical causes.

This may be temporary or permanent, and in either case sets us a problem, the true understanding of which is locked up in the family pedigree.

We find, likewise, that certain individuals tend to die by the lungs, others by the heart, others by failure of the kidneys to perform their work, and still others by the brain. If we are able to determine the existing tendency to death in an individual, as may undoubtedly be done by a proper study of human pedigree, in the widest acceptation of that term, we shall be able to save three lives where we now save one.

As an example, take the following imperfect history: Johnnie Sammons, æt. 4½ years. Mother still living and healthy, with the exception of a proneness to faint from slight causes. Grandfather and father died of typhoid fever, same epidemic, the former from hemorrhage from the bowels, the latter from syncope on sitting up in bed. The oldest son died from asthenia following an attack of dysentery.

On the 4th of January the little fellow was attacked with diphtheria. Patches on uvula and one tonsil; thin, sanious discharge from nose. Temperature, 105.5° F.; pulse, 148. During the night dyspnœa was marked, suffocation seemed imminent, and on the morning of the 5th inst. Dr. —— performed tracheotomy, with great relief to the little patient. Although there was no lung complication, and the child was given concentrated food and stimulants freely, he sank rapidly, and died at 10.30 P.M. of the 5th, his demise being preceded by a few hours of intense restlessness, which was quieted by 10 grs. of chloral. The fever had been well controlled by quinine and aconite in large doses. Autopsy showed no inflammation of any organ save the larynx and pharynx. Heart dilated and filled with dark-colored blood.

Is there anything to be gained from a study of this case in its relation to pedigree and tendencies? Much. Here is a family, some members of which show a tendency to death by the heart; one of them is seized with diphtheria, successfully passes the first danger—that of suffocation—and succumbs to the second, death by the heart, under the use of certain drugs that are known to kill by the heart. We have, then:

(*a*) Presumable individual tendency to death by the heart.

(*b*) Known tendency of disease to death by the heart; and,

(*c*) The use of certain drugs that tend to kill by the heart (aconite, chloral).

What were the indications for treatment after the danger by suffocation was passed, and there existed no lung complication? Stimulants and nourishment. These he had. Drugs that directly stimulate a failing heart. These he did not have; at least not those that were the most called for. How much more light would have been shed upon this case by a full and accurate knowledge of the family pedigree!

The principle here involved applies to the treatment of all diseases, whether acute or chronic. Intercurrent accidents may, of course, somewhat modify disease or individual tendency, or both; but that in no way invalidates the claims of the main tendencies to our earnest attention.

The treatment of tendencies will, of course, be two-fold. Knowing the tendency of a disease to kill by the lungs, heart, or brain, as the case may be, we must have some cause for such tendency, and must treat the tendency producer as well as the tendency produced. For instance, if a patient has an intense fever that, by virtue of its processes, is destroying the nervous as well as muscular power of the heart, it would be foolish, indeed criminal, on our part to treat the tendency alone, viz., the failing heart-power, and not endeavor to reduce the fever by appropriate means.

A very important question naturally arises in this connection. Do those drugs which produce peculiar manifestations in certain persons in health produce the same in acute and chronic disease; and if so, how far are these drug idiosyncracies modified by, or how far do they modify disease tendency? Is there any key to tendencies to death hidden beneath personal susceptibilities to drug action? I think there is. For instance, it seems to be fairly well established that those individuals in whom syncope almost invariably follows the use of *small* doses of certain drugs that kill by the heart, would succumb more readily to other drugs having a similar action, or to disease having a similar tendency, than a person not so affected. A matter of this kind, to become firmly established, needs careful, scientific observation, and recorded experience in a large number of cases. Its bearing on the prevention and treatment of disease is readily seen by any one.

With reference to the question of human pedigree, I can readily understand how long a time would be required to establish it upon a sufficiently broad basis to make it of universal service. Much can be done by the physician now by causing to be kept in every family where he is a regular attendant a simple table of pedigree, extending as far back as reliable information can be had, and in educating the people up to that point where legislative action will be possible.

Physicians connected with our hospitals and large public institutions, those in the army and navy, and those connected with life insurance companies can do more to establish the matter upon a practical basis than those in private practice. Yet the latter should not, on that account, neglect it. Such statistics as would necessarily accumulate would, if of no other value, be of the utmost importance in the matter of prognosis and the study of longevity. Families would then be given the benefit of the highest attainable knowledge of their "constitutions" by their physicians; the word idiosyncrasy would no longer be a convenient cloak for ignorance; temperament would be a term having some actual meaning, and scientific accuracy and the practice of medicine would advance a step from the obscurity, confusion, and contradiction of empiricism to the light and order of rational, scientific medicine.

Dr. Thos. R. Pooley, of New York, has resigned his professorship in Starling Medical College. Dr. Geo. H. Fox, of New York, has also resigned his position in the same institution.

A PLEA AGAINST THE RESECTION OF THE RIBS IN EMPYEMA.

By CHARLES A. LEALE, M.D.,

NEW YORK.

Nearly every month, either in our American or foreign medical journals, are we informed of successful results following the resection of ribs when the thorax has contained pus, and when the removal of portions of the bony walls were supposed to be necessary before a cure could be accomplished, and recently,* in the *Birmingham Medical Review*, one of the surgeons of the Midland Free Hospital for sick children gives an account of "nine operations, four of the children having recovered with expansion of the lung and restoration of the excised rib; in three others all discharge has ceased, and the lungs are in various stages of expansion. Another case is 'doing well,' and the ninth, almost moribund when operated on, died six hours later from asthenia."

I have performed thoracentesis on a number of children, and never yet have I been convinced that a resection of the ribs was necessary, and I believe it to be a dangerous procedure.

An illustrative case of restoration of the lung and pleura after the pus had remained in the thorax for several weeks, which I reported to the New York Academy of Medicine in 1873:

Case XI.—Empyema. Girl, nineteen months old. Chest opened by incision. This child was first brought to my class for diseases of children at the Northwestern Dispensary, February 14, 1870, her mother saying that she had been in poor health for two months; that the little one cried from pain whenever her chest was compressed while being lifted. On examination, there was dulness over the entire right lung; the left lung was in good condition. On the following day I made an incision between the seventh and eighth ribs, introduced the curved portion of a male silver catheter, and, with a Davidson's india-rubber syringe, removed sixteen ounces of thick pus. During the operation the pain was very slight, and after the removal of the pus she felt much better.

The wound, which was valvular, was easily closed by three fine silk sutures, then covered with court-plaster immediately after the operation. On visiting her forty-eight hours afterward, the plaster was found to have dropped off. The stitches were removed; wound entirely healed.

September, 1870.—She was brought to my office, her mother saying that during the past summer she had had several attacks of diarrhœa, from which she recovered. The child was then in excellent condition, and on examining her, all the lobes of the right lung were resonant, performing the necessary respiratory function, there being no reason to doubt her entire recovery.

Fourteen months after the operation of thoracentesis the child died of acute enteritis, and the necropsy made on the following day, assisted by Dr. Harwood.—Body well nourished. As there had been no noticeable abnormal condition, except the inflammation of the bowels, the abdominal and thoracic cavities only were examined. No peritonitis; the mucous membrane of the bowels presented the appearances of recent acute inflammation, and cause of death. The left thorax and contents were normal. On removing the right lung, it was found to be adherent, at several points, by pleuritic bands; at the superior and posterior borders it was inflatable. Over its surface were visible several small deposits of fibrinated lymph. All the lobes were inflatable. On cutting into the parenchyma, the only abnormal conditions existing were four or five portions, about the size of small nutmegs, of simply compressed lung. There were no cheesy or tubercular deposits found in any part of the body.[*]

---

* London Lancet, Aug., 1880, p. 281.

By this case we see that not only long compressed pulmonary tissue can be restored, but that the pleura also, after weeks' contact with purulent matter, may be again made perfectly healthy, secreting serous membrane, and the remaining pleuritic bands of adhesion, with marks where old bands had been removed, clearly demonstrated the reparative power of not only the lung but its coverings.

I have reported cases where the accumulation of pus in the thorax of children has been so great that a dislocation of the clavicle has been produced before I had operated, yet by the removal of the intrathoracic pressure, by withdrawing the liquid, recovery has followed.

The great disadvantage of subjecting a child to such a heroic operation as the resection of ribs, simply for the purpose of permitting the thoracic walls to contract, is very justly, as the *London Lancet* recently pointed out in a very strong editorial article, to be condemned, as it adds several additional factors to prevent a cure, without at the same time adding anything to the simpler, safer, and more effective operation of uncomplicated thoracentesis.

Who can surpass the success of our own Dr. Bowditch, of Boston, who in a private communication to me stated, after having performed thoracentesis over 250 times, that he had never seen a single death caused directly by the operation. Could such a statement be made if, in his cases, he had removed portions of the ribs?

Then why leave the well-beaten tracks for unsafe ones at the risk of life, and as the editor of the *Lancet* not too forcibly put it, "That recourse to it is an admission of failure to obtain a 'cure,' the effect of which is in many cases as disastrous as the saving of a life at the expense of a limb."

It is now nearly ten years since I published the following conclusions as the results of my experience in thoracentesis, and the only addition made in subsequent operations has been the antiseptic precaution. They are as follows:

I would, as in tracheotomy and abdominal paracentesis, prefer to use the scalpel to open the chest.

1. As a safer procedure, knowing exactly what is being cut.
2. An incised wound is known to heal, if required, with greater certainty.
3. That by using a long, male silver catheter, the most dependent part of the chest can be emptied of its fluid contents, and there is no danger of pricking the lung from change of position or movement of the patient while the liquid is being withdrawn, as noted by Dr. Allbutt.
4. That when pus has commenced to undergo that change preparatory to absorption, the probabilities are that very little, if any, will be produced after the operation if the wound is immediately closed.
5. That, in closing the wound, under the above circumstances, the little atmospheric air admitted, and the small quantity of pus left, are very soon absorbed.
6. That if pus again accumulates in the chest, the operation is so easy, the pain so slight, and the closure so rapidly accomplished, that a repetition is nothing to be feared, and really causes less prostration than when a large incision is made, and possibly pus found with greater rapidity.
7. That atmospheric air, pus, and blood, even to the extent of about eight ounces, may be absorbed, and that the injured, compressed lung can again resume its normal condition, as so conclusively proven by recorded post-mortem examinations.
8. That when unhealthy decomposition has commenced, the wounds ought to be left open and the parts carefully disinfected.
9. That thoracentesis should oftener be performed for the quick removal of fluid from the chest, even as recorded during far advanced phthisis pulmonalis, when relief may be obtained, life prolonged, and painful death averted.

The resection of the ribs during the operation of thoracentesis has now been resorted to quite frequently during the past six years in America, Great Britain, France, and Germany, without adding to the safety of the patient, and in a large number of instances I firmly believe has been the means of long procrastinating an apparent recovery, while in others, death it appears has been the direct result.

ERGOT-POISONING.

By JNO. M. KEATING, M.D.,

CONSULTING ACCOUCHEUR TO PHILADELPHIA HOSPITAL; LECTURER ON DISEASES OF CHILDREN IN UNIVERSITY OF PENNSYLVANIA, ETC.

THE following case presents certain features of interest, and I do not remember to have read of one like it in any of our own or foreign journals.

I was engaged to attend Mrs. D—— in her confinement to come off the first week in the current month, as it eventually did.

The family had moved to the city from a country town some years ago, and Mrs. D. was placed under my care for uterine disease. She had some inflammatory trouble following a previous labor. After a short course of the usual treatment she entirely recovered, and soon after became a second time pregnant.

At the third month she over-fatigued herself by some house-cleaning duties, and a miscarriage resulted. I was absent from the city at the time, and upon my return at the end of the summer, found my patient relapsed into her former state, with side-ache, purulent uterine discharge, subinvolution and its accompaniments. Once more she regained her normal condition, and again became pregnant. As the uterus enlarged there were evidences of "binding down," probably from some old adhesions about the left ovarian region. For some weeks previous to confinement she was unable to leave the house, for the abdomen was very much enlarged. There was great flatulence, and the patient suffered continually from left sciatica. The child was a large one, but the pelvis was capacious.

Fearing some difficulty from uterine inertia, I explained her case to a medical friend, and urged her to send at once for him, should the messenger find me absent from my office. As is usual in these cases, the child came at an inopportune time, but my friend arrived early enough to save the patient considerable pain by the application of the short forceps of Simpson. The head had well descended, and was resting at the outlet, but the uterus was unable to contract sufficiently to produce expulsion.

---

[*] Transactions of the New York Academy of Medicine. Series 2, vol. i.

There were placental adhesions of great firmness, and in consequence more than the ordinary amount of hemorrhage.

At last the uterus was well emptied, the binder applied, and ʒ ij. of the fluid extract of ergot administered—this by the doctor himself.

The patient was left comfortable, with instructions to the nurse to send for the doctor at once in case of hemorrhage, and while the messenger was absent to give the patient ʒ ss. of the ergot every half-hour till the doctor's return. By a misunderstanding the ʒ ss. of ergot was administered every half-hour from the time the doctor left. I reached the house a few moments after the messenger had been sent in search of me, and found my patient presenting an appearance that was indeed alarming. The face was of a bluish tint, and she seemed in great pain. The pupils were dilated, the pulse was quick, very weak, and occasionally irregular; there was dyspnœa, nausea (no vomiting), buzzing in the ears, and at times a tendency to syncope. The skin was cool and clammy. I was informed that another baby was expected. Upon inquiry, I learnt that in all she had taken about ℥ ss. of the fluid extract of ergot (and this was afterward corroborated by the medical attendant from the amounts left in the bottle which he himself had brought to the house). I loosened the binder, lowered her head, gave her some whiskey, and stimulated the circulation by rubbing, and in the space of half an hour the severity of the symptoms had gradually passed, and patient was left to sleep off a dose of morphia and potass. bromide that was administered.

One of the most interesting features in the case was the powerful uterine contractions. This alone was so marked as to have silenced in my own mind any doubts as to the efficiency of ergot, had I ever been a sceptic on the subject.

CASE OF

COMPOUND DISLOCATION OF LOWER ARTICULAR END OF HUMERUS.

With Fracture of Internal Condyle.

By GEO. E. McDONALD, M.D.,
SCHENECTADY, N. Y.

On the evening of July 22, 1880, Harvey B——, aged 8, was brought to my office for the treatment of an injury of right elbow-joint, which had been produced about two hours previously by being thrown from a horse.

An examination under ether showed the following condition of the parts: The whole lower articular end of right humerus protruded through the soft parts on the inside of the arm, the internal condyle was broken off and missing, and all ligamentous and muscular tissues were as thoroughly removed from the bone, for fully two inches on the outside and to a less degree on the inside, as the most careful dissector could have done it. The artery and nerve were uninjured, the articular ends of both radius and ulna were not displaced, and the periosteum was intact except at the point of fracture of the internal condyle.

With some difficulty the protruded bone was replaced, two sutures were put in the upper part of the wound, the arm was placed on a rectangular splint, and an evaporating lotion applied. For five or six days there was considerable constitutional disturbance, not very great swelling of the part, but little pain, and but a slight discharge. The last named was so little I endeavored to increase it with poultices.

In ten days after commencing treatment I began passive motion, removed the splint in three weeks, and this morning, August 30th, the boy was in my office with wound entirely healed, the joint but very little enlarged, the motion of pronation and supination nearly perfect, and with not much restriction in any of the usual movements of the joint.

Progress of Medical Science.

Acute Idiopathic Perichondritis of the Nasal Septum terminating in Abscess.—Dr. Clinton Wagner reports a rare case of this disease in a well-known actress attached to a popular comedy-stage in New York. Patient complained of a boil in her nose. A hard, small, circumscribed swelling was found near the junction of the cartilaginous and bony septum in the left nostril, for which warm fomentations were advised. On the fifth day the nose was largely swollen, pitted on pressure, had a dark and dusky color; there was centrifugal pain extending into the frontal sinus and brow; no pus. Thirty-six hours later, or after the beginning of the sixth day, the nostrils were occluded by the swollen septum, respiration being carried on by the mouth. Temperature was 105°, pulse 145, and there was occasional delirium. Free incision of the septum through the left nostril was followed by the escape of a large amount of thick, creamy pus, with plugs of slough. No pus was obtained by an incision through the right nostril until several hours later. In a few hours, or after the beginning of the seventh day, patient showed a tendency to stupor and collapse. The incisions were found to be closed, and after reopening gave exit to an uninterrupted flow of pus for several hours. Temperature fell to 101°, pulse to 110. The patient convalesced slowly, and after several weeks took to the stage again.

This seems to have been a true abscess of the septum. Wagner carried the probe through the knife-wound into the suppurating cavity, and as high up as the vomer. The cavity was drained of pus by means of a Pravaz syringe, and was treated with injections of carbolic acid and intra-nasal compresses of cotton. The necrotic process did not extend beyond the junction of the cartilage with the vomer, which, Wagner thinks, explains the absence of deformity or asymmetry of the nose.

Wagner regards an acute idiopathic inflammation of the septum as very rare, it being his first case in a register of 4,000 cases of nasal trouble. When not the result of injury, perichondritis of the septum may accompany syphilitic and scrofulous rhinitis.

Emphasis is laid upon early and free incision, from fear of an ascending meningitis.—*Arch. of Laryngology.*

Treatment of Hemorrhoids by "Crushing."—Mr. Pollock, of St. George's Hospital, London, employs an operation for hemorrhoids, which he terms crushing, and for which he claims the advantage over the ligature and the clamp and actual cautery, of being much less painful while it is equally effectual. The painfulness of the two last-named operations has always been a great objection to their employment, and while considering whether any modified process likely to be followed by less pain could be substituted for them, Mr. Pollock's attention was drawn to the known fact that any thorough and instantaneous destruction of a part is usually comparatively painless. It occurred to him, then, that if a pile could be rapidly and effectually destroyed at its base, by some instrument which would crush the part included in its bite, the vessels of the crushed portion would not be very liable to bleed when the surface of the pile would be removed, and, the nerves being bruised by the proceeding, the pain would probably be trifling. Some two or three years ago he began to put these views in practice, and his experience with the operation has been amply satisfactory. In the earlier operations he was often not as successful in preventing hemorrhage as was desirable, probably on account of defective construction of the clamp, or of taking up in its grasp too much of the tissue of the pile at once. Still, the hemorrhage was never alarming and was always easily controlled by two or three ligatures. In his late operations with an improved clamp, occasionally one or two small vessels have bled after the base of the pile was removed from the grasp of the instrument. The hemorrhage in these cases would probably have ceased spontaneously, but a ligature was always applied to any suspicious point for the sake of cleanliness, and to avoid giving any cause for alarm. From the very first, however, the operation proved very successful in one important particular, viz., the pain following it was very insignificant. The slough shed after the application of the crusher is very thin, and the œdema is slight compared to what often occurs after the other operations. The final results in the cases operated on have been fully as good as those obtained by the ligature and the actual cautery.

Mr. Pollock uses a powerful clamp made for the purpose by Wright & Co., of London. The steps of the operation are as follows: the patient is prepared for the operation in the usual way; when he has been brought under the influence of ether, he is turned on his left side and his right leg is well flexed and fixed with a strap, which is carried under the knee and around the neck. The pile to be removed is then drawn well down, and the clamp is applied to its base and at once tightly and firmly closed by the action of the screw at the end of the handles. The portion of the pile which protrudes *inside* the lips of the clamp is then to be removed with curved scissors. The clamp should be kept applied to the stump of the pile for about a minute longer, or for a still longer period if the pile be large and thick. The process is of course to be repeated according to the number of masses to be got rid of.—*The Lancet*, July 3, 1880.

ON GLYCERINE IN FLATULENCE, ACIDITY, AND PYROSIS.—Drs. Sidney Ringer and Murrell state that they have found glycerine very useful in flatulence, acidity, and pyrosis. It is not an infallible remedy, but it proves very useful in the great majority of cases, and sometimes succeeds speedily where the commonly used remedies have completely failed. The cases of flatulence in which it has been used were cases of stomach flatulence; as it is so readily absorbed it could not be expected to influence the formation of wind in the colon. In some cases it removes pain and vomiting, probably like charcoal, by preventing the formation of acrid acids which irritate delicate and irritable stomachs. The glycerine probably acts by preventing some forms of fermentation and putrefaction, but it does not interfere with the digestive action of pepsin and hydrochloric acid. Hence, while it prevents the formation of wind and acidity, probably by checking fermentation, it in no way hinders digestion. The dose is one or two drachms before, with, or immediately after food. It may be given in water, coffee, tea, lemonade, or soda-water. In tea or coffee it may replace sugar. In some instances a cure does not occur till the lapse of ten days or a fortnight.—*The Lancet*, July 3, 1880.

HIGH TEMPERATURE FROM CONSTIPATION.—A patient in the Massachusetts General Hospital, while convalescing from a mammary abscess, suddenly developed one morning a temperature of 104.5° F. The abscess was rapidly healing, and the temperature during the preceding eight days had not risen above 99° F. The patient, however, had not had a movement from the bowels for four days. An enema of soap-suds was given, and in less than an hour after this had operated, the temperature fell to 100° F., and continued normal afterward. The patient made no complaint, nor was there any phenomenon of any sort to account for the high temperature, unless the constipation would do so. No remedy was used except the enema.—*Boston Med. and Surg. Journal*, Aug. 12, 1880.

CHLORAL-HYDRATE IN ATROPINE-POISONING.—Several cases of chloral-poisoning have been reported in which atropine proved decidedly useful, but the following case, which is reported by Mr. Trocquart, is the first one recorded in which chloral proved effective in the treatment of atropine-poisoning. A very powerful man, twenty-four years of age, took, to relieve an attack of tinnitus aurium, an infusion prepared by himself from a handful of belladonna leaves. Half an hour after taking the medicine, symptoms of violent poisoning appeared, and emesis was produced by tartar-emetic. After three hours, violent delirium set in and persisted with short pauses of four or five minutes' duration. Four grammes of chloral-hydrate were ordered, but the drug could not be administered internally, as the trismus was so severe that the patient's mouth could not be opened; five grammes of the drug were therefore administered by injection. The violent muscular spasms ceased soon afterward, and the patient rapidly became quieter, so that in a short time it was possible to give the chloral by the mouth. The patient passed a quiet night, and on the following morning complained only of great muscular weakness.—*Allg. med. Cent. Zeit.*, July 21, 1880.

THE PAINLESS CURE OF INTERNAL HEMORRHOIDS.—Dr. Reuben C. Vance, of Cincinnati, advocates a method of treatment for internal hemorrhoids (*Med. and Surg. Rep.*, May, 1880), which he claims to be both painless and effectual. As a general rule, when the tumors are uninflamed, the most sensitive part is a narrow band just at the base of the growth, where the lining membrane of the rectum is reflected on the hemorrhoid. This band may not be the tenth of an inch in width. The rectal walls just beyond this band are slightly more sensitive than the general surface of the rectum in the neighborhood. Tracing the sensibility of the tumor itself from the band encircling it at its junction with the rectum to its summit, it will be found that there is a rapid loss of all perception of painful impressions as we pass from base to summit, until finally, at the top of the tumor, a needle can be run through its apex without exciting any pain or at most but very little. Dr. Vance's treatment consists simply in passing a seton through this anæsthetic region. The treatment is only applicable in hemorrhoidal tumors which are not inflamed. The tumors also must be purely internal tumors, the deeper and larger the better. In passing the setons it is necessary that the tumors be completely extruded. This done by means of enemata of hot water, the uppermost tumor should be operated on first; the spot where sensibility is least should be sought, and a curved needle passed through it, care being taken not to go too deep, or to bring the needle out too far from where it is entered. By attending to these points, the needle is passed without pain; but, if passed too deep, or carried too far from the point of entrance, pain will be excited, and the rectum will contract and the tumor return. As soon as the needle is passed, the ligature is to be tied into a loop about six inches long; this loop will enable the surgeon to control the movements of the whole mass of tumors. A double ligature should next be passed through each of the other tumors, and the threads tied so that there is not more than an inch of loop in all. Finally, the upper tumor is to be drawn down by means of the double thread through it, and a knot tied in the latter so close to the tumor that all the setons may be alike in length. The superfluous thread should then be cut off, and the tumors returned within the anus. This done, the patient should be instructed to keep his bowels freely open, and, above all, to at once assume the recumbent posture should any pain develop in the parts. Cases vary widely in the disposition of the seton. In some this comes away within a fortnight, leaving an ulcer that continues open until the hemorrhoidal tumor disappears; in others, it remains until all the pathological products have been absorbed, and then drops out. If the seton sloughs out and the opening heals with some of the tumor still remaining, a new seton is to be passed, just as if none had ever been introduced. It takes from five to nine weeks to cure an average case by this method, but the patient can continue his ordinary avocations during treatment. This is said to be the method employed by certain irregular practitioners who have great reputations in rectal surgery, and who undertake to cure internal hemorrhoids "without pain or detention from business," and. of course, "without caustic or the knife."—*Walsh's Retrospect*, July, 1880.

Neuralgia of the Testis.—Prof. Wm. A. Hammond contributes an article to the *St. Louis Courier of Medicine*, May, 1880, on Neuralgia of the Testis, in which he relates the histories of two cases, which were successfully treated by a method not hitherto employed in this affection. The first patient, æt. 47, had suffered more or less severely for over fifteen months. He admitted that the affection was originally, in all probability, induced by excessive venereal indulgence, but insisted that since the inception of the disease he had been extremely temperate in this direction. There was no evidence of syphilis. The pain was of a sharp, lancinating character, not confined to the testicle, but extending up the cord as high as the external abdominal ring. The cremaster muscle was, during the continuance of the paroxysms, the subject of strong spasm. Walking increased the pain, and sometimes brought on a seizure. The patient had tried all sorts of treatment without relief, and Dr. Hammond had already given an unfavorable prognosis, when the idea struck him that possibly strong pressure applied to the spermatic cord, so as to compress the nerves, might arrest the spasms. He extemporized a compressor out of an ordinary test-tube holder and a strong India rubber band, and applied it while the patient was suffering from a severe paroxysm, so as to compress the cord as high up as possible. So far from adding to the pain he was suffering, the immediate effect was a decided amelioration, but after a few minutes the pain began to increase and soon became more intense than before. The pressure was then increased by squeezing the blades of the instrument together with the fingers, and the pain stopped at once. The instrument was kept applied for fifteen minutes longer. Six hours afterward there had been no return of the pain, and to the present date the patient has remained entirely free from all pain. Sensation, which was destroyed by the pressure, has returned to the scrotum and testicle, and there are normal erections and sexual desires. The other patient, æt. 38, had suffered from the neuralgia for three months, and at the time he came under observation his suffering was particularly acute. In this case there was no reason for suspecting excessive sexual indulgence or syphilitic infection as the cause; apparently it was due to exposure to cold. As in the other case, the right testicle was the seat of the disease. Walking, sitting, or standing aggravated the suffering, and only by lying down on his back did he obtain any marked alleviation. Since the inception of the malady, venereal desires had almost entirely ceased, and erections such as those caused at night by lying on the back, or by distention of the bladder, added greatly to the suffering. Pressure was applied to the cord by means of an apparatus similar to a lemon-squeezer, but so arranged that the blades could be brought closer together or separated by means of a screw passing through them. In this way the pressure could be more exactly adjusted than by the elastic bands used in the previous case, and could, moreover, be rendered much greater, as occasion might require. The cord was compressed strongly at first; there was some little local pain, chiefly in the skin of the scrotum, but the pain in the testicle was immediately arrested. After five minutes had elapsed, the blades were separated so as to allow the circulation to be resumed, but in five minutes they were tightened again; after another five minutes of strong pressure they were adjusted so as to permit the circulation to go on, but yet exert considerable force upon the nerves, and while thus arranged the patient fell asleep, the first undisturbed nap that he had had since the beginning of the disease. For several days afterward the testicle seemed to be numb, but the insensibility is evidently gradually disappearing. To be effectual in relieving the pain of a neuralgic testis, Dr. Hammond believes that the pressure must be strong enough to break up the axis-cylinder of the nerves. If less than this, the pain will be aggravated; doubtless, in time, the nerve is restored to a state of integrity, but how long a period is required for this purpose cannot yet be determined.

* * *

An International Congress was held on Aug. 21, at Brussels, under the presidency of the Count of Flanders, to consider various questions relating to the use of alcohol. The Congress was promoted by French and Belgian societies, having as their aim the strict limitation, if not the entire suppression of the employment of this agent, save as a medicine.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 18, 1880.

FORCED STATISTICAL RETURNS FROM PHYSICIANS.

To the credit of the medical profession, it must be said that it has never been backward in lending its aid in any matters tending to advance the interests of state medicine. On the contrary, in its eagerness to give advice and help, it has shown such a disposition to force its services upon the public, that the latter not only expect such services to be freely given, but actually demand them under a legal penalty for non-performance. These are facts with which medical men have been long familiar; but, nevertheless, few will read the letter of "M.D.," in another column, without feeling that great injustice is done to good intentions, and that, in respect to the subject under consideration, the physician discharges more than his share of obligation to the commonwealth. It is well known that much of his professional services goes to the balance of charity, and of this not a small proportion to the direct benefit of the state, for which he virtually gets nothing in return. This may, for the sake of the argument, be considered a matter of choice, as is certainly the case with the service in such hospitals as are referred to by our correspondent, and in which patients abundantly able to pay receive first-class medical attendance for nothing. As has been truly said, the attendant can resign if he does not wish to continue his connection with the institution under such conditions. This is so entirely a matter of personal choice with the physician or surgeon so attending, that the remedy is in his own hands. Not so, however, with his relations to various local and state boards, so far as the furnishing of vital statistics and other kindred subjects are concerned. As a citizen, special and exceptional services are demanded of him, for which the State has no right to ask, and which in equity should not be rendered without some pecuniary return for them. And yet we are informed that the late conference on vital statistics hesitated to take any action in the direction of acknowledging in a suitable manner the valuable services so freely rendered to the various bureaux of the country by the members of the medical profession.

All the work which is forced upon the physician by law can be viewed in no other light than that of imposition. As a citizen, he must do his part in maintaining the government—in paying taxes, in conforming to such laws as tend to the benefit of the greatest number; but in all this he bears the common burden. When, however, services of a special character are demanded of him, for the ability to perform which he has had a special training, and for the rendering of which he is to receive nothing, the law very clearly oversteps its true prerogative. It is proper that registration of births should be made, and that all other vital statistics should be systematically collected; but why this labor should be saddled upon the general practitioner, and that, too, under the penalty of a heavy fine for neglect to do the same, does not appear.

If no one else could be found to do this work, there would then be some excuse for selecting physicians for the purpose. But then the physician is under no possible obligation to give these services to the state; on the contrary, the fact of their special value would impose a pecuniary obligation on the part of the state. As it is, however, most, if not all, of the duties imposed upon the physician by health boards can be intelligently performed, under his direction at least, by the parties whom he is attending. For instance, the parents should attend to all the necessary details in reporting the birth of a child, in giving notice of the appearance of contagious diseases in the family, and all other kindred matters. This may be considered part of the duties of citizenship, and the parties more directly interested should be compelled to perform them. Our correspondent very properly, in this connection, refers to the fact that very many births occur without professional attendance, when not even a midwife is present. The law does not compel a pregnant woman to obtain professional assistance; consequently, except that the parents of children are made responsible for correct returns of birth, there is a liability that the records will be incomplete. There is no more reason why the physician should be compelled to report the occurrence of contagious diseases in the families he may attend, than he should be to report every child he may deliver. In neither case is he paid for the time and trouble in so doing, while in many instances, by complying with the law concerning contagious diseases he may attend, he may lose many of his best patients. Patients are very loathe to believe that it is necessary for the family physican to act as a detective for a health board, and thus cause the forcible removal of a patient to a pest-house. And yet the physician is expected to do this—to place himself in a false position with his patient, to jeopardize his future attendance upon the family, or else subject himself to a comparatively heavy legal penalty.

It is right and proper that contagious diseases should be reported, and that the management of epidemics should be entrusted to sanitary boards; but why should physicians, more than any other class of citizens, be compelled to make such reports, not only without compensation therefor, but under penalty of a fine? After he has made his diagnosis of the disease, the responsibility of reporting it to the health authorities should be left with the family itself. If the family would willingly run the risk of evading such a law, it should do so at its peril. That such reports would not be made otherwise than by the physician in attendance is hardly an argument for compelling him to do so by law. Of course we are viewing the subject from the standpoint of justice to the physician as a citizen, in compelling him by law to do more than his share of public work.

If it could be claimed that the physician, by virtue of his vocation, has some special privileges granted to him by the state, he might in turn be willing to give certain services to the state by way of compensation. But the condition of any such service does not exist. On the contrary, the state does little or nothing to protect the physician in the practice of his profession. The history of all legislation proves that the state is inclined to favor the quacks rather than the regulars, under the plea that otherwise it would be encouraging class legislation. But this part of the subject needs no discussion in this connection; it is sufficient for our present purpose to protest against compelling the physician by law to do, in the line of his professional business, special services the like of which is not demanded of other citizens without suitable remuneration. It is hardly an excuse for the health boards to assume that because the physician may take a special interest in preventive medicine that he should be forced to do extra work at the sacrifice of time and money. The members of these boards are, almost without exception, well paid themselves, and are generally ready to ask for special appropriations when any new law enlarges the scope of their duties. But we have yet to hear of any appropriation being made or asked for by such boards, in order that a normal fee should be paid the physician for sending in his reports, thereby offsetting his liability to fine for failing to do so. There is without doubt a deep feeling in the profession against this mode of forcing services from its members, and the remarks of our correspondent are timely in inviting a more general discussion of the subject.

ON THE RELATION OF MUSCLE AND NERVE.

THERE have recently appeared in the columns of the RECORD a series of articles, by Dr. Thomas Poole, on the Relation of Muscle and Nerve. Our contributor has offered a new explanation of the mode in which nerve-impulses affect muscular tissue. The old theory that the nerve conveys an active stimulus to the muscle, which stimulus causes a contraction, does not seem satisfactory to Dr. Poole. He argues that what the nerve really carries is a paralyzing impulse. It is, he says, the natural tendency of muscle to contract. This tendency is inhibited by the nerves which go to it. When we desire a muscle to contract, an order is sent out from the central nervous system for the end-plates on the muscles to let go their hold. Electricity and other artificial stimuli, so-called, are considered to be really paralyzing agents, or suspenders of inhibition. The failure of muscles to contract at once when cut off from their cerebro-spinal centres is due, presumably, to the inhibitory power retained in the nerves themselves and their peripheral plates. As these gradually lose their power, the phenomena of secondary contractures and rigor mortis set in. The new theory, according to our contributor, offers a satisfactory explanation of the above phenomena. It also explains the various post-mortem muscular movements, as well as the cramps and convulsions that often accompany the diseases or the ingestion of poisons, which lessen or suspend the activity of the nervous centres. We cannot, of course, do justice to the theory in any brief presentation of it. We have, however, given its main points. These Dr. Poole has elaborated with great ingenuity and industry in his different papers; and he has gathered together many physiological facts which make his articles well worth the reading.

As far as the hypothesis is concerned, however, we are obliged to say that he has not yet demonstrated it; and, furthermore, that we do not believe he ever can. With the kindest feelings toward our esteemed correspondent, facts compel us to say that he does not seem to have thoroughly mastered his subject, and that he has not even treated it in a properly scientific manner.

On this account we do not care to go into any elaborate rebuttal of the various arguments that have been presented in our columns. Dr. Poole has shown that there are a number of phenomena in the physiology and pathology of the nervous system which are not yet explained. In this way he has rendered a genuine service by his labor. We can say no more for it.

The relations of muscle and nerve and the phenomena of muscular contraction are still points in physiology that are not wholly settled. A statement of such facts as are pretty definitely known, however, will be sufficient to show the weakness of the inhibitory theory of Dr. Poole, and will not, perhaps, be devoid of freshness to many of our readers who are presumably somewhat rusty in their physiological studies.

In the first place, it is known that a muscle can contract when irritation is directly applied, without the intervention of nerves. In living organisms, however, under normal conditions, muscle never does contract except through the medium of the nerves. If the motor nerves are entirely paralyzed by curare, muscle does not contract, as would be the case if these motor nerves had the inhibitory power asserted by Dr. Poole.

When a nerve is stimulated at any point, an impulse passes down it at the rate of about ninety-four feet per second, and, dividing up with the nerve itself, is distributed to the end-plates on the muscle. From these points the impulse is transformed, and passes along the muscular fibre in each direction from the end-plates. It goes in the form of a wave, at the rate of about ten feet a second. Accompanying this wave are molecular changes in the muscle, and with these is developed a slight electrical current. Following only $\frac{1}{100}$ of a second after this first wave, and at the same rate of speed, comes the wave of muscular contraction. The physical changes in a muscular contraction are well known. The molecular changes consist probably in a translocation of the molecules, causing the shape of the muscle-cell to be changed. There is, with this, an explosive decomposition, which results in the production of heat, carbonic and sarcolactic acids, as well as other chemical substances in very slight amount. Dr. Austin Flint, Jr., believes that urea is produced by and is a measure of muscular action. Urea, however, is not found in tetanized muscle; and the amount of nitrogenous product from muscular contractions is extremely small. The above are the phenomena of a single muscular contraction; if no impulse succeeds this single one, the muscle, which is perfectly elastic, returns to its condition of rest. In order to secure a permanent contraction, impulses at the rate of at least 19.5 per second must be sent into it from the central nervous system, or from whatever the point of stimulus chosen. The contracted muscle of a man is therefore always vibrating and giving out the same musical note, *i.e.*, one indicating 19.5 vibrations per second. This may be heard by listening with the stethoscope over the contracted biceps for example. It was argued by Dr. Poole that the rigor mortis represents the natural contraction of the muscle when relieved of its nervous inhibition. This is not the case, however; in rigor mortis there is no note of vibration, and there is a coagulation of the muscle-plasma, with the production of myosin. Myosin does not exist in living contracted muscle. There are certain physical changes which we need not enumerate, but which distinguish the phenomenon of rigor mortis from that of a regular muscular contraction. They are essentially different conditions.

The electrical phenomena which accompany a nerve-impulse and muscular contraction are highly interesting, and point away from any hypothesis of inhibition. Whether there are natural nerve- or muscle-currents is a disputed question. The theory that muscular contraction is an electro-motive phenomenon has the support of DuBois Raymond and others. At the recent meeting of the American Association for the Advancement of Science, the President, Dr. G. F. Barker, gave a quasi-endorsement to the electrical theory of Dr. Radcliffe, which makes the muscle-cell a veritable Leyden jar. We are inclined to doubt the value of these views; but, whatever their importance, it is well established that an electrical current is excited when the nerve sends an impulse to the muscle, and that just as this nervous impulse strikes the muscle, a similar, though stronger electrical current, starts up in that tissue. Whatever be the nature of "nerve-force," or "muscle-force," they are too much alike for us to consider the former a paralyzing and the latter an active contracting agent.

We may not have said enough upon the present matter to make clear the absolute inefficiency of Dr. Poole's hypothesis; we have, however, given enough of the facts regarding muscular irritability to allow the reader to reason out a condemnation if he chooses. We fear that, even as it is, there is need of some apology for arguing at length against what may appear utterly trivial, and in presenting facts that are already too familiar. The waves of "inhibitory" hypotheses, however, are becoming unpleasantly numerous. Dr. Brown-Séquard is struggling in the midst of them. He, indeed, has done such magnificent physiological work that we can forgive him a great deal; but the profession looks less kindly toward others. And Dr. Poole is inhibition gone mad.

THE AMERICAN GYNECOLOGICAL SOCIETY.

At the concluding session of the American Gynecological Society recently held in Cincinnati, the retiring president, Dr. Sims, took occasion to say that the meeting had been an unprecedented success. The research shown by the papers, the vigor displayed in the discussions, as well as the hearty hospitalities offered by the resident profession, had combined to make the occasion a very gratifying one. The reports that have been furnished us seem to justify this verdict. There were a number of papers that showed much labor, and nearly all awakened active debates.

The President, in his annual address, made a vigorous attack upon some of the defects in the constitution of the society. He urged that its membership be enlarged, that the restrictions regarding admission be less rigid, and that the policy of the society be more liberal. It should, he thought, look more kindly toward the work of the younger men.

The papers that were read dealt for the most part on large themes. Dr. Battey described the indications for the operation that goes by his name. Laparotomy, Quinine in Pregnancy, Trachelorrhaphy, The Position of Women during Labor, and Ulcerations of the Cervix, were among the topics discussed.

The proceedings of the society received more than usual attention from the local reporters. Some of these seemed to be impressed with a personal interest in the speakers, and pen-pictures of our leading gynecologists, graphic and flattering, were daily presented to the reading public of Cincinnati.

The attendance at the meeting was not large, not quite half of the members being present. This did not, however, at all dampen the enthusiasm. Professor W. H. Byford was chosen president for the ensuing year, and the society adjourned to meet next year in this city.

THE MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE annual meeting of this association is one of the most important scientific events of the year. It deserves some notice, therefore, from medical men, even though few of the subjects discussed relate directly to the medical sciences. The recent meeting at Boston was an unusually large one, and it was successful in every way. Nearly a thousand persons were in attendance, two hundred and eighty papers were read, and five hundred and sixty-seven new members were elected. Several members of the medical profession, who have distinguished themselves in physiology and other sciences, were made fellows. A Section on Biology was created, which insures for the future a larger number of papers bearing on medical science.

A report, found elsewhere, gives some of the more interesting features of the occasion. The annual address of Professor Barker is an able presentation of some of the problems relating to the phenomena of life. It was generally characterized by the daily press as a great oration, but we doubt if careful scientists will pronounce the same verdict. The address showed, we think, more of the bias of the chemist than of the knowledge of the physiologist. It is true, as Professor Barker asserts, that the phenomena of life are becoming more and more explained by known physical and chemical laws. But the actions of special organs cannot yet be expressed in the simplicity of chemical equations. It is too soon to say that emotion is a molecular vibration whose intensity can be measured by the plethysmograph. Neither is it at all settled that muscle is an electrical machine and its contraction a somewhat clumsy electro-chemical phenomenon. It will seem, we believe, to physiologists that there was just a little too much freshness to Professor Barker's pictures of vital processes.

The address of Professor Agassiz before the Natural History Section, and that of Professor Le Conte before the Entomological Club, were each better productions, from a scientific point of view, than was the oration of the President.

Taken with certain other recent scientific contributions, including especially the work of Professor Huxley on the crayfish, they show a certain change of attitude, which naturalists are now assuming, on the subject of the development of vegetable and animal forms. There was a time, not long ago, when every voice was strident in advocacy of evolution. Now, evolution is assumed as an established fact, and scientific effort is directed to explaining the many difficulties that lie in the way of the special applications of the hypothesis. This is the better and truer spirit; for, to increase our knowledge, we need research and not polemics.

A large number of the papers were on practical subjects, and many of the discussions had a popular interest. These were not, however, in excess, and, on the whole, the American Association can feel that its last annual session has done good work in promoting the interests of science.

THE SOCIAL SCIENCE ASSOCIATION.

THE American Social Science Association held its annual meeting in Saratoga last week. The object of this Association is the somewhat magnificent one of discussing measures for the perfection of society and the promoting of millennial conditions. This naturally puts a very wide field before the Society. At its annual meetings the range of subjects is extremely great, and some ridicule has been excited by the apparently miscellaneous character of the essays. The Society, however, professes no Utopian views, and it is winning a solid reputation for itself on account of its able and practical contributions to the science it aims to promote. Some of the best men of the country are now among its members, and its annual meetings rarely fail to furnish much that is new and instructive. It is gratifying to note an increased attention to the various branches of state medicine. A number of interesting papers relating to this subject will be found reported in another column.

◆

THE GOLD MEDAL OF THE BRITISH MEDICAL ASSOCIATION has been awarded to Dr. Wm. Farr, F.R.S., D.C.L., C.B., as an expression of their high opinion of his long, unwearied, and successful labors in behalf of statistical and sanitary science, as a recognition of the light he has thrown upon many physiological and pathological problems, and on account of the extraordinary service his work has rendered to the health of nations.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 21, 1880.

Dr. T. E. Satterthwaite, President, in the Chair.

Dr. Shrady presented on behalf of a candidate a specimen of cancer of the kidney. The patient from whom it was removed was a female child without any hereditary history of cancer, and in the enjoyment of good health up to February of the present year, at which time the mother noticed a tumor in the left hypochondriac region. This, the mother thought, might in some way have been connected with a slight fall upon the carpet, occasioned by a misstep during the previous month. But this, in the opinion of Dr. D. C. Cocks, the attending physician, was without the proper relation of cause and effect.

The tumor grew so rapidly that when the presenter was called in the body of the child measured twenty-one inches around the umbilicus. The tumor was rapidly encroaching upon the right side, and marked a line of dulness to about the region of the eighth rib. Before death this measurement was increased to twenty-seven inches. The average temperature throughout the whole illness was 100½°. The urine contained no albumen nor blood. The swelling, upon being pierced by the hypodermic syringe, gave exit to blood only. This being microscopically examined by Dr. Draper, was found to contain neither casts nor cells.

The diagnosis of malignant disease of the kidney was based upon the rapidity of growth and the fact that the colon was detected anterior to the tumor. At a subsequent stage Drs. W. C. Livingston and Aikens tested the contents of the tumor by aspiration, and also obtained blood only.

At the autopsy the diaphragm on the right side was found pushed up to the fourth rib on the left, and the third rib on the right side. The apex of the heart was between the second and third ribs, with the base at the sterno-clavicular junction. The tumor, which was kidney, was found adherent to the spleen by friable adhesions, and to the greater portion of the abdominal walls. The right kidney, with the exception of slight hypertrophy, was found to be healthy. Secondary deposits were found in the liver.

The microscopical appearances were those usually to be found in this form of cancer, to wit, an abundance of cells, together with free nuclei and very little intervening tissue. The presence of normal kidney structure determined the organ attacked. The mass in gross was soft, almost to pulpiness, even diffluent in character.

DISSECTING ANEURISM OF THE AORTA—RUPTURE INTO RIGHT PLEURAL CAVITY.

Dr. Peabody exhibited a specimen of dissecting aneurism, removed that day from the body of a man 39 years of age, a native of the United States, unmarried, a clerk by occupation. He was admitted to the New York Hospital on the 17th of May. He had been a hard drinker, but had never had rheumatism or syphilis. He gave a good history of chancroid and clap. Denied all history of injury or straining, etc. He was well up to two years ago, since which time he had had many symptoms of gastric dyspepsia. For several months he had suffered from severe pain in the back and right side. Four months prior to admission he noticed a hard pulsating tumor in the epigastric region just to the right of the median line.

On admission this tumor was very distinct. It measured six inches vertically by four and a half inches from side to side. It had no distinct expansile pulsation, but had a distinct double murmur. He was put upon Tuffnell's treatment of restricted diet and kept in bed. Under this treatment his pain decreased so that he was able to get along without narcotics, and in fact was feeling tolerably comfortable. He continued doing well up to the second of this month, when he suddenly experienced severe pain in the region of the lower lobe of the right lung posteriorly. He soon began spitting blood, and his temperature rose to 100°. He became quite weak. In this condition he remained until this morning, when he suddenly died in collapse without having exerted himself in the least.

The autopsy was made four hours after death.

Just below the diaphragm and occupying the site of the cœliac axis and superior mesenteric, there was found an aneurismal sac large enough to contain a hen's egg of large size. It contained both recent and old laminated clots, of which the latter alone remain. Its walls wherever exposed are very atheromatous, as is the aorta also below the aneurism. Near the lower part of the sac on the anterior surface is seen a ragged rupture half an inch long, through which the blood has made its way between the laminæ of the media upward into the loose cellular tissue of the posterior mediastinum. Here, about two inches above the diaphragm, it forced its way through a large opening into the right pleural cavity, where 2,300 cubic centimetres of pure blood were found. Beginning over the body of the first lumbar vertebra, the aorta, after becoming again narrowed, again enlarges, forming a sac considerably larger than the one just described. Beneath it the bodies of the last three dorsal vertebræ and that of the first lumbar are deeply eroded.

A recent hemorrhagic infarction was found in the lower lobe of the right lung. The heart is normal in size, but its muscular tissue is more deeply pigmented than usual. The valves are competent. The other organs were normal.

Dr. Delavan presented

PLASTER CASTS OF CONGENITAL MALFORMATIONS OF THE HAND.

The first was from a case in which the deformity was not hereditary. The left forearm was normal to the wrist, the carpal bones were fused together, and at the top of this single bone were five small bud-like projections, on two of which were attempts at the formation of nails. The other specimen, from a child two and a half years of age, contained but a thumb and forefinger, all the other bones of the fingers being absent. There was but one bone in the forearm and that was the ulna.

Dr. Tausky presented a specimen of

EPITHELIOMA OF THE VAGINAL PORTION OF THE CERVIX UTERI,

removed by Piffard's galvano-cautery.

Dr. Lewis Smith presented a specimen of

MYXO-SARCOMA OF THE KIDNEY.

removed from the body of a child, the history of which he gave as follows:

About the middle of May, I was called to see a child who was nineteen months old and was still nursing. The mother stated that its health had been good up to the age of twelve months, when it had a broncho-pneumonia which was pretty severe, from which, however, it fully recovered. Three months later it suffered another attack of the same disease, but likewise recovered therefrom without any serious complication. From that time the mother stated that the child seemed to droop. At the time of my visit I found a moderate febrile movement, the temperature being from 101° to 102° F. The examination of the child for the first few days was negative in character. Then some distention of the abdomen showed itself. There were no marked evidences of meteorism; percussion was somewhat dull, and there was no tenderness on pressure. On the left side there were evidences of the existence of a tumor. This I supposed to be splenic in character, although the patient had not been out of the city, and had not suffered from any malarial troubles. I could trace the hardness up to the ribs, and down as far as the crest of the ileum and the median line. Dr. Clark, who happened to be in the neighborhood, examined the child and concurred in the opinion that the tumor was due to enlarged spleen. When he pressed upon the kidney of that side he found that the organ touched the tumor or was continuous with it. The urine was scanty, and at times contained albumen. There was nothing else of special interest in regard to the history of the case. The child, during its illness, showed an especial aversion to farinaceous food. The evacuations contained mucus and streaks of blood. The child gradually sank and died of exhaustion June 11th.

At the autopsy the left kidney was absent and its place occupied by the tumor. The pancreas was also absent. The spleen was normal, but was dislocated somewhat by the pressure of the tumor. The small intestines, in one or two places, were adherent to the tumor and to the liver.

Dr. Heitzmann examined the tumor and expressed the opinion that it was a myxo-sarcoma of the kidney. **Dr. Smith** thought that, aside from the question of diagnosis, a very interesting feature in the case, in connection with the absence of the pancreas, was the marked aversion on the part of the child for farinaceous food.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Twenty-ninth Annual Meeting, held at Boston, Aug. 25th, 26th, 27th, 28th, 30th, 31st, and Sept. 1st, 1880.

[Special report for THE MEDICAL RECORD of papers relating to Medical Science.]

One of the most notable of the addresses was that by the retiring President, **Professor George F. Barker**, on some aspects of

THE PROBLEM OF LIFE.

The address was an exposition of the extent to which physicists and physiologists had already been able to reduce vital phenomena to chemical and physical processes. Prof. Barker tried to show that the muscle was a machine, and that its contraction was an electrical phenomenon rather than the exhibition of "vital irritability."

DISCUSSING THE NERVOUS SYSTEM AND ITS FUNCTIONS, he said:

"One function yet remains which cannot be altogether omitted from our consideration. This function is that of the nervous system. In structure this system is well known to all. In composition it is made up essentially of a single substance, discovered by Liebreich and called protagon, the specific characters of which have lately been confirmed by Gamgee. In function the nerve-cell and the nerve-fibre are occupied solely in the reception and the transmission of energy, which is in all probability electrical. There is evidently a close analogy between the nerve and the muscle, the axis-cylinder, like the fibrilla, being composed of cells, and having a positive electric charge upon the exterior surface, which has a tension of one-tenth of a volt. Haughton attributes *tinnitus aurium* to the discharge of nerve-cells.

The higher functions of the nerve-cell, those connected with mental processes, is a field too vast to be entered at this time. The double telegraph line of nerve, motor and sensory in their effect, but, as Vulpian has proved, precisely alike in function, are the avenues of ingress and egress. Every sensory impression is received by the *thalami optici;* every motor stimulus is sent out from the *corpora striata.* In the acts denominated reflex, the action goes from the spinal cord, and is automatic and unconscious. Should the impression ascend higher to the sensory ganglia, the action is now conscious, though none the less automatic. Finally, should deliberation be required before acting, the message is sent to the hemispheres by the sensory ganglia, and will operate to produce the act. Based on principles which can be established by investigation, a true psychology is coming into being, developed by Bain, Maudsley, Spencer and others. A physiological classification of mental operations is being formed which uses the terms of metaphysical psychology, but in a more clearly defined sense. Emotion, in this new science, is the sensibility of the vesicular neurin to ideas. Memory, the registration of stimuli by nutrition. Reflection is the reflex action of the cells in their relation to cerebral ganglia. Attention is the arrest of the transformation of energy for a moment. Ratiocination is the balancing of one energy against another. Will is the reaction of impressions outward. And so on through the list.

It will be seen that the distinguished orator is much surer of our knowledge of the nervous system than are most physiologists or neurologists.

He shows a still greater and more dangerous confidence in his endorsement of

CRANIAL THERMOMETRY AND OF THE PLETHYSMOGRAPH.

His remarks, which follow, show a pleased enthusiasm rather than the critical spirit which should characterize the president of a great scientific association; for surface thermometers and plethysmographs may indicate all that is claimed, but the scientific value of their results cannot yet be confidently accepted.

Another important fact concerning nervous action is that its amount may be measured by the quantity of blood consumed in its performance. Dr. Mosso, of Turin, has devised an apparatus called the plethysmograph—drawings of which were exhibited at the London apparatus exhibition of 1876—designed for measuring the volume of an organ. The forearm, for example, being the organ to be experimented on, is placed in a cylinder of water and tightly enclosed. A rubber tube connects the interior of the cylinder with the recording apparatus. With the electric circuit by which the stimulus was applied to produce contraction were two keys, one of which was a dummy. It was noticed that, after using the active key several times, producing varying current strengths, the curve sank as before on pressing down the inactive key. Since no real effect was produced, the result was caused solely by the imagination, blood passing from the body to the brain in the act. To test further the effect of mental action, Dr. Pagliani, whose arm was in the apparatus, was requested to multiply 267 by 8, mentally, and to make a sign when he had finished. The recorded curve showed very distinctly how much more blood the brain took to perform the operation. Hence, the plethysmograph is capable of measuring the relative amount of mental power required by different persons to work out the same mental problem. Indeed, Mr. Gaskell suggests the use of this instrument in the examination room, to find out, in addition to the amount of knowledge a man possesses, how much effort it causes him to produce any particular result of brain-work. Dr. Mosso relates that while the apparatus was set up in his room in Turin, a classical man came in to see him. He looked very contemptuously upon it, and asked of what use it could be, saying that it couldn't do anybody any good. Dr. Mosso replied, 'Well now, I can tell you by that whether you can read Greek as easily as you can Latin.' As the classicist would not believe it, his own arm was put into the apparatus and he was given a Latin book to read. A very slight sinking of the curve was the result. The Latin book was then taken away and a Greek book was given him. This produced immediately a much deeper curve. He had asserted before that it was quite as easy for him to read Greek as Latin, and that there was no difficulty in doing either. Dr. Mosso, however, was able to show him that he was laboring under a delusion. Again, this apparatus is so sensitive as to be useful for ascertaining how much a person is dreaming. When Dr. Pagliani went to sleep in the apparatus, the effect upon the resulting curve was very marked indeed. He said afterward that he had been in a sound sleep and remembered nothing of what passed in the room—that he had been absolutely unconscious; and yet every little movement in the room, such as the slamming of a door, the barking of a dog, and even the knocking down of a bit of glass, were all marked on the curves. Sometimes he moved his lips and gave other evidences that he was dreaming; they were all recorded on the curve, the amount of blood required for dreaming diminishing that in the extremities. The emotions, too, left a record. When only a student came into the room, little or no effect appeared in the curve. But when Professor Ludwig himself came in, the arteries in the arm of the person in the apparatus contracted quite as strongly as upon a very decided electrical stimulation. In an address of the retiring president of this association, delivered but a few years ago, I find this sentence: 'Thought cannot be a physical force, because thought admits of no measure.' In the light of the rapid advances lately made in investigating mental action, we see that in two directions at least, in its rate of action and of its relative energy, we may already measure thought, as we measure any other form of energy, by the effect it produces."

THE ANNUAL ADDRESS BY PROFESSOR ALEXANDER AGASSIZ,

before the Section on Natural History, was a model of scientific essay-writing. Taking a single genus of animals, the echinoderms, he traced their palæontological history and compared this with their embryological history. His conclusions were that it was impossible for naturalists to follow back the genealogy of living beings and say, with any certainty, what were their ancestors.

In the Subsection on Biology, which was permanently organized on the third day, a highly interesting contribution to vegetable pathology was given by MR. T. J. BURRILL, in a paper entitled

ANTHRAX OF FRUIT-TREES.

He stated that the widespread disease of the pear-tree, known as fire-blight, and that of apple-tree, known as the twig-blight, are due to a common cause. This is a living organism which produces butyric fermentation of the material stored in the cells, especially those of the liber. The organism is similar to, if not identical with, the butyric vibrione of Pasteur, and the *bacillus amylobacter* of Van Tieghem. It assumes various shapes during development, but its characteristic form is that of two oblong joints with rounded ends, the proportions of each joint being .002 mm. by .003 mm. They are shorter and thicker than the bacterium termo, and move more slowly. A large number of experiments resulted in showing pretty conclusively that these organisms conveyed the disease from tree to tree. The most conspicuous change in the tissues of the affected plant, revealed by the microscope, is the almost total disappearance of starch from the cells.

PROFESSOR BURT G. WILDER, of Cornell University, presented three essays upon the

STRUCTURE AND NOMENCLATURE OF THE BRAIN,

with special reference to that of the domestic cat. Professor Wilder is a firm believer in the great usefulness of the cat as a subject for anatomical work, and has in preparation a work upon the subject as a practical introduction to human and comparative anatomy. The titles of the three essays are as follows: "Partial Revision of the Nomenclature of the Brain;" "The Foramina of Monro in Man and in the Domestic Cat;" "The *Crista Fornicis*, a Part of the Mammalian Brain apparently not hitherto described."

Prof. Wilder's plan for reforming the nomenclature is something as follows: Since technical terms, he says, are the tools of thought, and the best workman prefers the best tools, anatomical nomenclature should be made as perfect as possible. That the nomenclature of the brain needs revision is evident from the great number of names applied to the same part, from the length and complexity of some names, and the inappropriateness of others. It is proposed, therefore, to discard all vernacular names, to make a selection of the shorter technical ones, to abbreviate some names by the omission of unessential words, and others by the substitution of prefixes for adjectives. For example, the single word *iter* is substituted for "aqueduct of Sylvius" and "iter a tertio ad ventriculum quartum." *Callosum* takes the place of "*corpus callosum*," and *fimbria* of "corpus fimbriatum;" for the ponderous terms "*corpora quadrigemina anteriora*" and "*posteriora*," Professor Wilder substitutes *preoptici* and *postoptici*. As to descriptive terms, like Barclay, Owen and others, Professor Wilder urges the adoption of terms referring to the longitudinal axis of the vertebrate body, and the rejection of such as apply to man in his erect attitude. By the use of *dorsal, ventral, cephalic, caudal, lateral, dextral, sinistral, mesial, ental, ectal, proximal, distal,* with their adverbial forms, *dorsad, ventrad,* etc., and the various possible combinations, all ambiguity may be avoided. The test of description is *not that* *it may direct, but that it cannot mislead.* Most of the proposed names are already in use. A few new ones are required to designate parts either unknown before or insufficiently recognized. Two of these, *crista fornicis* and *carina fornicis*, apply to elevations of the fornix found in the cat, sheep, and man, and do not appear to have been observed before. The new term *aula* (a hall or court) is given to the cephalic (anterior) part of the third ventricle between the *foramina of Monro*, or passages leading into the lateral ventricles. Professor Wilder regards the aula as of great morphological importance, and promises an essay on it at a future meeting. The foramina of Monro, so called in honor of the second Alexander Monro, Professor Wilder thinks should be more carefully studied than is usual, partly from their physiological and pathological aspects, but chiefly because the recognition of their existence is indispensable to a clear conception of the general relations of the ventricles and their walls. Their smallness in man and most other mammals, and the poor preservation of the parts in most alcoholic brains, seem to have interfered with their correct description, and Professor Wilder thinks he has for the first time accurately defined their boundaries, especially the dorsal boundary at the point of intrusion of the plexus.

Mrs. Richards read a report on

FOOD ADULTERATIONS.

Her inquiries covered only flour, sugar, bicarbonate of soda, cream of tartar, and baking-powders. The results of her investigations were very like those which have been heretofore made. She found very little adulteration, and that was comparatively harmless. Cream of tartar was the worst, and baking-powders next.

A report was read by **Mr. E. B. Elliott**, on a uniform system of

REGISTERING DEATHS, BIRTHS, AND MARRIAGES.

This uniformity is wanted he said: 1, for the better disposal of property, all of which changes hands at least once in twenty-five years; 2, to ascertain the relative salubrity of localities; 3, to determine the values of all interests based upon the duration of life, the tables now used being in the main of European origin.

Dr. B. Joy Jeffries read a paper on

COLOR-BLINDNESS,

which excited considerable interest, although nothing especially new was told. Four per cent. of males were, he said, color-blind. Only 10 out of 13,893 females examined were found so affected. This is due, perhaps, to ages of instruction in color which women have received. Age, race, color, education, condition of civilization, climate, all seem to have nothing to do with color-blindness. It is congenital, largely hereditary, and handed down through the females, though they escape it. It may be artificially produced by putting a patient in a hypnotic state; also those color-blind who can be put in this state may be temporarily relieved of their defect. It is incurable by any known practicable means, but it has been cured by tobacco and alcoholic poisoning, by injuries to the head, and by brain disease. It is sometimes a symptom of brain disease. It can be helped by gaslight, or by looking through pale lemon-colored glass, or a solution of fuchsine.

The following papers, bearing more or less directly on medical science, were read: "Comparative Anatomy as Part of the Medical Curriculum," by Harrison Allen; "Microscopical Investigations of the Havana Yellow Fever," by Dr. G. M. Steinberg. This paper gave, essentially, facts already more or less known. "Plan of the Cerebro-spinal System," by S. V. Clevenger.

Professor W. O. Atwater, in an essay on the nutritive value of fish, gives the following table. Taking medium beef at 100, we should have, as the nutritive value of like weights of fish free from bone: Medium beef, 100; fresh milk, 23.8; skimmed milk, 18.5; butter, 124.0; cheese, 155.0; hen's eggs, 72.0; codfish, fresh, 68.0; flounders, 65.0; halibut, 88.0; striped bass, 79.0; bluefish, 85.0; mackerel, 86.0; lake trout, 91.0; eels, 95.0; shad, 99.0; whitefish, 103.0; salmon, 104.0; salt mackerel, 111.0; dried codfish, 346.0.

A paper was read by **Dr. C. S. Minot**, "On the Summation of Muscular Contractions;" and one by **W. K. Brooks**, "On the Rhythmical Character of Segmentation."

ANNUAL MEETING OF THE AMERICAN SOCIAL SCIENCE ASSOCIATION.

Held at Saratoga, Sept. 7th, 8th, 9th, and 10th, 1880.

(Special Report for The Medical Record.)

The annual summer meeting of this association was opened by President **D. C. Gilman**, of Johns Hopkins University, Baltimore, who delivered an address on "The Purposes of the American Social Science Association." These were summed up as follows:

The aim of this association has been declared to be a study of the conditions which tend to make a perfect state of society where "each is for all and all is for each," and the discovery of those laws of coöperation which will secure to every individual his highest development. It is obvious that the inquiry is very complex, and will never be completely answered. Surely, this great problem must be much subdivided before any progress can be made in its solution. To begin with, all those subjects which pertain to the physical well-being of the community must be considered, and this includes not merely sanitary regulations, as they are commonly understood, but the freedom to exchange the products of one region for that of another. Next, morality, or social order, deserves consideration—the conditions of society which are favorable to temperance, chastity, honesty, frugality, industry, and quiet. Intellectual culture and the study of all the agencies which promote mental power next demand attention—our systems of education, direct and indirect, high and low. Finance comes next. Though the sanitary, the moral, and the pedagogical laws are understood, if the finances of a community are crooked, nothing will go straight. The currency is the route on which we all travel, and if that leads down a chasm, down go we all, though the rails be plated with silver. Sound legislation based upon wise jurisprudence must also be secured, and with good written laws must come good customs and usages. It is a wide field, we must acknowledge, which the association aims to cultivate, but if ever it shall be subdued it will be an earthly paradise—an enchanted ground.

One of the subjects most fully discussed was that of the education of children and of women. The subject was opened with a paper by **Col. T. W. Hig-**

GINSON on the kindergarten system. This he commended, but added a list of possible

DANGERS OF THE KINDERGARTEN SYSTEM.

As the system is rapidly spreading through this country, medical men ought to be familiar with such of these alleged dangers as may affect especially the physical condition of the child.

There is, said the speaker, the danger of overstimulating the brain in a manner injurious to and incompatible with child-life. This arises, in a measure, from the fact that the disposition of the child's time is made by persons of mature age and strength, who can seldom rightly gauge and estimate the importance of frequent changes and variety of occupations and the place that absolute idleness and repose hold in the healthy development of all children. As says Margaret Fuller of the forcing process insisted upon by her father in her own education, "Children should not cull the fruits of reflection and observation early, but expand in the sunshine and let thoughts come to them." The child, when left largely to its own resources, often defends itself from a tension of mind at once premature and injurious. There is the danger of overstimulating the nervous system, by which the digestion sometimes becomes so much weakened as to seriously interfere with the proper nourishment of the child's system, a danger the more perilous as the teacher is not likely to know of such a result until the family physician or the dispensary doctor is called upon for counsel when the difficulty has become a serious matter. And there is the danger of straining the eyes, a trouble whose symptoms are unknown to the pupil, and often unsuspected by the teacher. The sight of children in some instances has thus been permanently impaired.

In a later discussion, as to the proper time for children to begin to go to school, PRESIDENT GREGORY, of Illinois, expressed his belief that if children were kept out of school until nine or ten years old, at fifteen or sixteen they would be in advance of those who began school earlier. He said he had had experience, and this was his conclusion from several examples within his own knowledge.

A paper was read by MISS EDITH SIMCOX, giving an account of the educational work in England, especially that done for women. The subject of

MEDICAL CO-EDUCATION

was incidentally brought up, and MR. M. D. CONWAY related some of his experiences in the matter. He told the story of how Miss Garrett, now Dr. Garrett-Anderson, had to study medicine surreptitiously at the gates of Lock Hospital, and showing how the cause of female education had been advanced step by step, without any really serious opposition. The first lecturers repeated the lectures given to men's classes to those of women, but finally one professor said he could not repeat his lectures. If men and women could sit together in churches and theatres, he thought they could do so without harm to hear class lectures. Mr. Conway thought that in a few years the co-education of the sexes in the colleges and universities of England would be an assured fact.

In the Health Department, DR. D. F. LINCOLN, who presided, made an address on

THE NATIONAL BOARD OF HEALTH.

This, he said, had been in existence only eighteen months, and was brought forward to meet a national calamity by the yellow fever at Memphis, which the local authorities could not manage. It was called into existence in haste. Coming into existence under adverse circumstances, the Board had, by great exertion, become an assured success. The great and blind reliance upon quarantine had been done away with, and local cleanliness had been enforced. Great difficulty had been found at first in obtaining information and finding channels therefor, and, consequently, the Board could not deal intelligently with the epidemic of 1879 in Memphis. It is almost wonderful that a practical and right conclusion had been reached so soon when it is remembered that the American Public Health Association, which met in November, 1878, was prevented from giving any decisive expression of opinion as to the line of action to be followed, by lack of information regarding the epidemic which had scourged Memphis during the past season. Thanks to measures of local cleanliness, advised by the National Board of Health, Memphis is now a clean city, and it will be almost impossible for it to be again scourged by yellow fever.

In the same department a paper was read by its secretary, DR. E. W. CUSHING, on

REGULATING THE PRACTICE OF MEDICINE

by statute law. Within the past ten years, he said, laws to regulate medical practice in this country have been urged, and passed by various legislatures. The burden of proof of the necessity of such laws has been wholly with the promoters of these laws, as it must be admitted that all restrictive laws are in themselves bad, and only to be tolerated if they appear less bad than the evils which they are intended to remove. In Massachusetts such a law has been defeated, partly from strife between medical societies and much from the opposition of spiritualistic, clairvoyant, and magnetic interests, which are numerous, well organized and powerful in that State. The writer still hopes that some practical law may be evolved there which shall prove of public utility by really elevating and regulating the practice of medicine.

One of the best papers read before the Association, was that by DR. WALTER CHANNING, on the

TREATMENT OF THE INSANE,

in its economic aspect.

Dr. Channing said there is a true as well as false economy in the treatment of the insane. Any measure which will, in fact, cure or shorten mental disease, and thus shorten the time of treatment of the insane, may be regarded as in the interest of true economy. Such measures may be an expense for the moment; but, if they build a foundation for the more successful treatment of insanity in the future, they serve the proper end. Insanity is promoted by conditions which are favorable to the extinction of other diseases as well as public evils. The advance of civilization points out scientific principles which enable us to struggle successfully against and exterminate diseases which could not be formerly understood. Yellow fever for centuries was a scourge which could not be annihilated, but modern science has furnished the weapons to check its ravages. Insanity may be regarded as the residue resulting from intellectual and moral progress of the nineteenth century. Mankind gradually but steadily improves in cultivation, in art and science. Still, insanity increases. It is a lamentable fact that cures are effected less frequently, and the disease is apt to result in permanent weakness. Why is this? Why is one person out of every two or three hundred doomed to mental wreck. There is evidently some grave defect in this great social fabric, and to discuss its true nature becomes daily a more important duty. The truest economy will be that which traces insanity back to its origin and saves future generations from its terrible infliction. To understand the disease we should know the laws of physical and moral health. Yet, of all branches of the science of medicine, psychology is least taught and least understood. Good care will effect much in the treatment of insanity, and thirty to forty per cent. of recoveries are at present had in insane hospitals. Physicians have great facilities for studying and understanding mental and physical peculiarities, and therein are the most powerful weapons for combatting insanity. They have not, however, turned their attention enough in this direction.

ADDITIONAL PSYCHOLOGICAL STUDY NECESSARY.

It is one purpose of this paper to urge the importance of the study of psychology or psychological medicine by medical men. This subject has been generally neglected in medical schools. Students should have a thorough knowledge of brain anatomy and histology. The various terms of psychology should also be familiar to them and the pathological appearances of the brain should be learned from frequent dissections, and with this should be combined a knowledge of the spinal cord and nerve. A proper course of psychological lectures should extend over two years, and with this should be combined frequent recitations, as lectures are of little use except followed by recitations. In many instances weak men have succeeded to strong ones, and been content to follow methods heretofore pointed out, rather than to pursue and carry on further investigations, and therefore reactions have followed in regard to the treatment of insanity. The best-informed writers estimate that of eleven persons who become insane six recover and five die during the attack. Of the six who recover, not more than two remain well during the balance of their lives, the other four sustaining renewed attacks, from which two at least die. Superintendents of asylums say that more time is needed for proper treatment, and if this is so it should be granted. Physicians should also be increased. Medical schools should also have the advantages resulting from having the hospital near at hand. In closing, he urges the importance of the study of the pathology of insanity, and suggests that each patient in an insane hospital should have his whole history recorded while an inmate, so that after his discharge it would present a tolerably complete picture of his disease and treatment while therein.

A paper was read by **PROF. S. W. JOHNSON**, of Yale College, on the

ADULTERATIONS OF FOODS, DRUGS, AND DOMESTIC ARTICLES.
